CONTENTS

Preface	xli
----------------	------------

VOLUME 1

Chapter 1	Limb Lengthening by Combined Technique (External Fixator and Flexible Intramedullary Nailing): Experimental Studies <i>Dmitry Popkov and Arnold Popkov</i>	1
Chapter 2	Influence of the Transphyseal Sliding Nailing on Longitudinal Growth of the Tibia: Experimental Studies <i>Dmitry Popkov, Natalia Kononovich, Roman Shutov and Dominique Barbier</i>	13
Chapter 3	Lengthening and Deformity Correction of Lower and Upper Limbs <i>Pierre Lascombes, Arnold Popkov, Pierre Journeau and Dmitry Popkov</i>	29
Chapter 4	Influence of Lengthening on the Residual Limb Growth <i>Pierre Journeau, Dmitry Popkov and Pierre Lascombes</i>	51
Chapter 5	Bioactive Implants in Reconstructive Orthopedics <i>Arnold Popkov</i>	69
Chapter 6	Use of Intramedullary Bioactive Nailing in Deformity Correction in Patients with X-Linked Hereditary Hypophosphatemic Rickets <i>Arnold Popkov</i>	89
Chapter 7	Hybrid Technologies in Spinal Deformity Surgery <i>Sergey Ryabykh</i>	103
Chapter 8	Management of Posttraumatic Nonunions and Bone Defects by Combined Techniques (Ilizarov External Fixation and Interlocking Intramedullary Nailing). Experimental Studies and Clinical Practice <i>Dmitry Borzunov, Alexander Mitrofanov, Sergey Kolchin, Andrey Emanov and Elena N. Gorbach</i>	121

Chapter 9	Complications of Bariatric Surgery, Improvement of Comorbidities and Impact on Quality of Life <i>Jaime Ruiz-Tovar and Carolina Llaveró</i>	137
Chapter 10	Adjustable Gastric Banding Surgery: Impact on Inflammation and Iron Metabolism <i>Cristina Catarino, Susana Coimbra, Luís Belo, Luís Monteiro, Elísio Costa and Alice Santos-Silva</i>	163
Chapter 11	Long Term Diabetes Outcomes after Bariatric Surgery <i>Richard W. Carroll, Jeremy D. Krebs and Rinki Murphy</i>	185
Chapter 12	Anesthesia Consideration and Management for Bariatric Surgery <i>Antoni Sabaté and Sandra Llauro</i>	209
Chapter 13	Small Intestinal Bacterial Overgrowth after Bariatric Surgery <i>Iman Andalib, Naveen Gara, Bikram S. Bal, Timothy R. Shope and Timothy R. Koch</i>	219
Chapter 14	Optimal Physical Activity and Exercise Following Bariatric Surgery <i>Matthew D. Barberio, Rosemary Lu and Monica J. Hubal</i>	235
Chapter 15	Pregnancy after Bariatric Surgery <i>Catarina Policiano, Alexandre Valentim Lourenço, Luísa Pinto and Luís Mendes Graça</i>	253
Chapter 16	History and Development of Percutaneous Vertebral Augmentation Procedures <i>Vincenzo Salini and Francesco Saverio Sirabella</i>	267
Chapter 17	Thoraco-Lumbar Spine Anatomy <i>Rosa M. Mirapeix</i>	271
Chapter 18	Etiopathogenesis of Pathological and Traumatic Vertebral Fractures <i>Vincenzo Levi and Mauro Pluderi</i>	277
Chapter 19	Biomechanical Evaluation <i>Daniele Vanni and Vincenzo Salini</i>	281
Chapter 20	Epidemiology of Adult Thoracolumbar Fractures <i>Luigi Aurelio Nasto and Enrico Pola</i>	285
Chapter 21	Surgical Options for Thoracolumbar Vertebral Fractures <i>Daniele Vanni, Vincenzo Magliani and Renato Galzio</i>	289
Chapter 22	Vertebroplasty and Kyphoplasty: Role and Limits <i>Daniele Vanni, Vincenzo Magliani and Renato Galzio</i>	295
Chapter 23	Types, Morphology and Function of the New Devices <i>Daniele Vanni and Vincenzo Magliani</i>	299
Chapter 24	VBS: Evaluation and Indications <i>Daniele Vanni and Vincenzo Magliani</i>	305

Chapter 25	Spine Jack: Evaluation and Indications <i>Daniele Vanni, Vincenzo Magliani and Vincenzo Salini</i>	313
Chapter 26	Osseofix: Evaluation and Indications <i>Marcello Bartolo, Giovanni Grillea and Giovanni Nano</i>	321

VOLUME 2

Chapter 27	Surgical Technique <i>Daniele Vanni, Vincenzo Magliani and Renato Galzio</i>	329
Chapter 28	Alternatives to PMMA for Vertebral Augmentation Procedures <i>Daniele Vanni and Vincenzo Salini</i>	343
Chapter 29	Stem Cells and Biotechnologies for Vertebral Augmentation Procedures <i>Andrea Pantalone, Matteo Guelfi and Vincenzo Salini</i>	349
Chapter 30	Brow Lift <i>Richard Baker and Afshin Mosahebi</i>	353
Chapter 31	Blepharoplasty <i>Mano Sira</i>	377
Chapter 32	Facelift <i>Fulvio Urso-Baiarda and Rajiv Grover</i>	393
Chapter 33	Rhinoplasty <i>Samuel Hahn and Oren Friedman</i>	421
Chapter 34	Mastopexy <i>Daniel Marsh and Niri Niranjani</i>	453
Chapter 35	Breast Augmentation <i>Patrick Mallucci and Olivier Alexandre Branford</i>	469
Chapter 36	Breast Reduction <i>Gurjinderpal Singh Pahal and Venkat Ramakrishnan</i>	495
Chapter 37	Liposuction <i>Reza Nassab</i>	517
Chapter 38	Botulinum Toxin <i>Darren J. McKeown</i>	537
Chapter 39	Facial Fillers <i>Darren J. McKeown</i>	559
Chapter 40	Body Contouring Using Implant Prostheses <i>Daniel Saleh and Mohammed Riaz</i>	579
Chapter 41	Cosmetic Surgery in the Adolescent Patient <i>Kelsey Larson, Sidhi Gosain and Arun Gosain</i>	593

Chapter 42	Hand Rejuvenation <i>Kuen Chin and Fulvio Urso-Baiarda</i>	611
Chapter 43	Body Dysmorphic Disorder <i>Valerie Picavet and Peter Hellings</i>	631
Chapter 44	Development of a Surgical Navigation System Based on 3D Slicer Using Augmented Reality (AR) Technology <i>Xiaojun Chen and Lu Xu</i>	645

VOLUME 3

Chapter 45	Application of Navigation System in Bimaxillary Surgery <i>Sun Yi and Constantinus Politis</i>	665
Chapter 46	Computer-Assisted Minimally Invasive Surgery: Image-Guided Interventions and Robotic Surgery <i>Francisco M. Sánchez Margallo and Juan A. Sánchez Margallo</i>	679
Chapter 47	Modified Methods of Setting Up the Spinal Navigation System <i>Sang Hoon Jang and Ho-Yeon Lee</i>	719
Chapter 48	Ultrasound Imaging for Robotic Orthopedic Surgery: A Survey <i>Pedro M. B. Torres and Paulo J. S. Gonçalves</i>	727
Chapter 49	Development of Scrub Nurse Robot (SNR) Systems for Laparoscopic Surgery <i>Kitaro Yoshimitsu</i>	737
Chapter 50	T-Cell Shape Variation with Intra-Cellular Ca ²⁺ Concentration: A Joint Image and Shape Study <i>Yi Gao, Wei Chen, Baoyu Liu, Allen Tannenbaum and Cheng Zhu</i>	749
Chapter 51	Revisional Bariatric Surgery for Weight Regain: A Programmatic Approach <i>Eric J. DeMaria and Meredith A. Grzybowski</i>	757
Chapter 52	Metabolic Failures and Bariatric Procedures <i>Pedro Paulo Caravatto, Tarissa Zanata Petry and Ricardo Cohen</i>	763
Chapter 53	Diagnostic Tools in Failed Bariatric Procedures <i>Rudolf Weiner, Islam A. El-sayes and Sylvia Weiner</i>	773
Chapter 54	Adjustable Gastric Band Failures <i>J. W. M. Greve</i>	799
Chapter 55	Failed Sleeve Gastrectomy <i>Ricard Corcelles and Antonio Lacy</i>	811
Chapter 56	Reoperations for Roux-en-Y Gastric Bypass Failures <i>Jacques M. Himpens and Ramon Vilallonga</i>	821

Chapter 57	Failed Minigastric Bypass: Surgical Strategies <i>Jean-Marc Chevallier</i>	843
Chapter 58	Surgical Procedures for Failure of Biliopancreatic Diversion with Duodenal Switch (BPD-DS) <i>Simon Marceau, Simon Biron, Frédéric-Simon Hould, Stefane Lebel, Odette Lescelleur, Laurent Biertho and Picard Marceau</i>	861
Chapter 59	Failed BPD <i>Giuseppe Maria Marinari, Vincenzo Borrelli and Luc Lemmens</i>	869
Chapter 60	History of Subarachnoid Haemorrhage <i>Dieter H. Woischneck</i>	877
Chapter 61	Arterial and Venous Vascularisation of the Brain <i>Horst Claassen</i>	885
Chapter 62	Neuropathologie of Subarachnoid Haemorrhage <i>Angelika Scheuerle</i>	905
Chapter 63	Subarachnoid Haemorrhage <i>Stefan Röhrer</i>	913
Chapter 64	Risk Factors: Formation, Growth, Rupture <i>Karl-Michael Schebesch and Petra Schödel</i>	917
Chapter 65	Scales <i>Petra Schödel and Karl-Michael Schebesch</i>	921
Chapter 66	Symptoms, Extracranial Manifestations <i>Petra Schödel and Karl-Michael Schebesch</i>	927
Chapter 67	Admission, Diagnostic Imaging, Acute Hydrocephalus <i>Thomas Schmidt</i>	931
Chapter 68	Endovascular Treatment of Aneurysms. Pre-, Peri- and Post- Interventional Management <i>G. Friedrich Götz</i>	945
Chapter 69	Aneurysms: Surgical Therapy <i>Ralph König</i>	957
Chapter 70	Decompressive Craniectomy and Aneurysmal Subarachnoid Haemorrhage <i>Stefan Röhrer</i>	967
Chapter 71	Intensive Therapy I for SAH <i>Thomas Kerz</i>	971
Chapter 72	Neuroprotection: DCI, Vasospasm, Nimodipine <i>Christian Heinen</i>	979

VOLUME 4

Chapter 73	Intensive Care: Monitoring <i>Werner Klingler and Dirk Repkewitz</i>	991
Chapter 74	Endovascular Treatment Options for Cerebral Vasospasm after Spontaneous Subarachnoid Haemorrhage <i>Yigit Ozpeynirci and Bernd Schmitz</i>	1001
Chapter 75	Chronic Hydrocephalus after Subarachnoid Haemorrhage <i>Alexandra Huthmann and Christoph A. Tschan</i>	1019
Chapter 76	Epileptic Seizures in Association with Spontaneous Subarachnoid Haemorrhage <i>Sarah Jesse</i>	1027
Chapter 77	Neurorehabilitation after Subarachnoid Haemorrhage <i>Martin Schorl and Michael Hartwich</i>	1035
Chapter 78	Cognitive Plasticity after Spontaneous Subarachnoid Haemorrhage <i>Christine Brand</i>	1057
Chapter 79	Health-Related Quality of Life Following Spontaneous Subarachnoid Haemorrhage as an Assessment Criterion for Therapeutic Outcome <i>Thomas Kapapa</i>	1063
Chapter 80	Experimental Models for the Study of Subarachnoid Haemorrhage <i>Nicole A. Terpolilli</i>	1069
Chapter 81	Vascular Imaging <i>Athanasios Saratzis</i>	1079
Chapter 82	The Role of Imaging in Colorectal Surgery <i>M. G. Pramateftakis, A. Kalogera-Fountzila, K. Sapalidis and E. Kotidis</i>	1091
Chapter 83	The Role of Imaging in Breast Surgery <i>Vasileios N. Papadopoulos</i>	1109
Chapter 84	The Role of Imaging in Neurosurgery <i>Savvas Grigoriadis, Christine Karatziou, Maria Sidiropoulou, Athanasia Anastasiou, Eleni Tsatsali and Georgios Giakoumettis</i>	1159
Chapter 85	The Role of Imaging in Parathyroid Surgery <i>I. Koutelidakis, A. Doundis, A. Ananiadis, S. Kalaitzis, T. Kaltsikis and V. Papaziogas</i>	1193
Chapter 86	The Role of Imaging in Adrenal Surgery <i>K. Sapalidis, I. Anastasiadis, E. Kotidi, M. G. Pramateftakis and I. Chrysogonidis</i>	1207
Chapter 87	The Role of Imaging in Hepatobiliary Surgery <i>Polyxeni Agorastou, Andreas Tooulas and Georgios Tsoulfas</i>	1223

Chapter 88	The Role of Imaging in Pancreatic Surgery <i>A. Mastoraki, N. Economopoulos, I. Papanikolaou and N. Arkadopoulos</i>	1233
Chapter 89	The Role of Imaging in Esophageal Surgery <i>Efstathios Kotidis, Konstantinos Sapalidis and Manos-Georgios Pramateftakis</i>	1295

VOLUME 5

Chapter 90	The Role of Imaging in Gastric Surgery <i>Efstathios Kotidis, Manos-Georgios Pramateftakis and Nikolaos Michalopoulos</i>	1323
Chapter 91	The Role of Imaging in Urology <i>Michelle Kim, Douglas A. Mata and Dicken S. C. Ko</i>	1341
Chapter 92	The Role of Imaging in Plastic Surgery <i>Alexandros Mekras and Vasileios Kalles</i>	1357
Chapter 93	Wrist Fractures in Adults: What Should a Medical Student Know? <i>Fares E. Sayegh</i>	1369
Chapter 94	Minimally Invasive Midface Lift Using Absorbable Sutures with Cones: A Step by Step Procedure <i>M. Goisis, A. Di Petrillo, L. Rosset, A. Kunderfranco, S. Mele, E. Stella and S. Khabouri</i>	1377
Chapter 95	Free Flap Breast Reconstruction: New Updates and Refinements on a Well Established Technique <i>Cedric L. Hunter and Gordon K. Lee</i>	1405
Chapter 96	New Materials and Techniques in General and Digestive Ambulatory Surgery <i>J. M. Suárez Grau, Dra. S. García Ruiz, Dra. C. Mendez García, C. Rubio Chaves and F. Docobo Durántez</i>	1429
Chapter 97	Ambulatory Surgery: Anesthetic Management and Complications <i>Monica del-Rio-Vellosillo and Jose Javier Garcia-Medina</i>	1443
Chapter 98	Ambulatory Surgery in Orthopaedics: Prevalence, Complications and Long-Term Outcomes <i>Omar Faour Martín and Miguel Ángel Martín Ferrero</i>	1463
Chapter 99	Advances in Surgical Procedures Thyroid Goitres: Surgery for Large and Difficult Goitres <i>Yassar A. Qureshi and Fiona McClenaghan</i>	1473
Chapter 100	Electrical Stimulation for Improving Physical Fitness Pre- and Postoperatively after Abdominal Surgery <i>Artur Marc Hernández</i>	1485

Chapter 101	Scenario Based MCQs in Oral Surgery <i>Arun Priya Srinivasan, Namdeo Prabhu and Mohammed Kassab</i>	1513
Chapter 102	The Role of Surgery in the Treatment of OSAS <i>F. Lorusso, A. Battaglia, A. Mistretta and S. Gallina</i>	1533
Chapter 103	Laparoscopic Surgery In Situs Inversus <i>Pankaj Kumar, Tushar S. Mishra and Siddhant Sarthak</i>	1559
Chapter 104	Management of Surgical Wounds Infections in Spine Surgery <i>M. Dobran, D. Nasi, S. Veccia and A. Giacometti</i>	1569
Chapter 105	Historical Evolution of Conservative Surgery of Breast Cancer <i>Maria Antonia Vaquero-Pérez, Jesus S. Torres-Jimenez and José Manuel Ramia-Ángel</i>	1577
Chapter 106	Surgery of Colorectal Liver Metastases Involving the Inferior Vena Cava <i>Mario Serradilla-Martín, Pablo Ruíz-Quijano, Ana Palomares-Cano and José M. Ramia-Ángel</i>	1587
Chapter 107	Multidisciplinary Approach to Gender Reassignment Surgery in a DSD 46XX Patient with Delayed Diagnosis of Congenital Adrenal Hyperplasia: A Case Report <i>K. Sumapradja, R. A. Putri, A. K. Harzif, C. L. Sukasah and S. D. Elvira</i>	1599
Chapter 108	Cerebrovascular Bypass Surgery in the Treatment of Brain Aneurysms <i>Goran Mrak, Jakob Nemir and Hrvoje Barić</i>	1609
Chapter 109	Indocyanine Green Video-Angiography with FLOW 800 Analysis: Applications in Neuro-Oncological Surgery <i>Morgan Broggi, Jacopo Falco, Costanza M. Zattra, Marco Schiariti, Ignazio G. Vetrano, Giovanni Tringali, Giovanni Broggi, Paolo Ferroli and Francesco Acerbi</i>	1631

VOLUME 6

Chapter 110	The Application of Indocyanine Green Videoangiography as an Adjunct for Arteriovenous Malformation Surgery <i>Ann Knoll, Dara Sam Farhadi, Megan Cadigan, Joseph Georges and Peter Nakaji</i>	1653
Chapter 111	Current Trends in Functional Muscle Transfer to Improve Outcomes in Facial Reanimation Surgery <i>Ioana Lese and Adriaan O. Grobbelaar</i>	1665
Chapter 112	The Role of Endoscopic Sinus Surgery in Pediatric Patients <i>Marco Berlucchi and Michele Tomasoni</i>	1679

Chapter 113	Femtosecond Laser-Assisted Refractive Surgery <i>Hui Sun</i>	1709
Chapter 114	Surgery in Malignant Pleural Mesothelioma: Extra-Pleural Pneumonectomy – A Critical Appraisal <i>Luca Bertolaccini and Lorenzo Spaggiari</i>	1721
Chapter 115	Guided Tissue Regeneration in Maxillofacial Surgery <i>Francine Benetti, João E. Gomes-Filho, Gustavo Sivieri-Araújo, Rogério de C. Jacinto, Elói Dezan-Júnior and Luciano T. A. Cintra</i>	1729
Chapter 116	How to Prevent Orthopedic Complications and Early Surgery in CP Children: Role of Botulinum Toxin Therapy <i>Vera Zmanovskaya, Elena Levitina and Svetlana Ushakova</i>	1753
Chapter 117	Nutritional Care in Children with Cerebral Palsy. Perioperative Management of Patients with Cerebral Palsy Undergoing Orthopedic Surgery <i>Anna Shaitarova, Olga Perfilova and Elena Khramova</i>	1765
Chapter 118	Single-Event Multilevel Orthopedic Surgery in Children with True Equinus Gait and Jump Knee Gait <i>Sergey Leonchuk, Georgy Chibirov, Tamara Dolganova, Dmitry Dolganov and Dmitry Popkov</i>	1779
Chapter 119	Distal Rectus Femoris Transfer as a Part of Single-Event Multilevel Orthopedic Surgery <i>Georgy Chibirov, Orhan Gatamov, Tamara Dolganova, Dmitry Dolganov and Arnold Popkov</i>	1793
Chapter 120	Single-Event Multilevel Orthopedic Surgery in CP Patients with Natural and Iatrogenic Crouch Gait <i>Tamara Dolganova, Georgy Chibirov, Orhan Gatamov, Dmitry Dolganov and Dmitry Popkov</i>	1801
Chapter 121	Reconstructive Hip Surgery as a Part of Multilevel Surgery in Non-Ambulant CP Children. Hip Development after Reconstructive Surgery <i>Ahmed Tomov, Georgy Chibirov, Sinisa Ducic, Arnold Popkov and Anna Aranovich</i>	1815
Chapter 122	Percutaneous Endoscopic Gastrostomy: Historical Perspective <i>Jeffrey L. Ponsky</i>	1831
Chapter 123	Indications, Contraindications, Decision Making and Informed Consent <i>Robert D. Fanelli and Josephine A. Fanelli</i>	1837
Chapter 124	Palliative Considerations of Gastrostomy <i>Julie L. Mitchell and Susan A. Glod</i>	1847

Chapter 125	Preoperative Management <i>Valerie Wu Chao Ying and Jose M. Martinez</i>	1861
Chapter 126	Anesthesia for PEG Tube Placement <i>S. William Hazard, III</i>	1871
Chapter 127	Diagnostic Endoscopy during PEG <i>Susan M. Wetzel, Mei Chris Huang and John D. Mellinger</i>	1885
Chapter 128	Percutaneous Endoscopic Gastrostomy: The ‘Pull’ Technique <i>Kyle L. Kleppe and Melissa Phillips LaPinska</i>	1907
Chapter 129	Percutaneous Endoscopic Gastrostomy: The ‘Push’ Technique <i>Keyur Parikh and Richard C. K. Wong</i>	1921
Chapter 130	Percutaneous Endoscopic Gastrostomy: Introducer Technique <i>Sean B. Orenstein</i>	1931
Chapter 131	Direct Percutaneous Endoscopic Jejunostomy <i>Mena Boules, Andrew Strong and Matthew Kroh</i>	1947
Chapter 132	PEG with Jejunal Extension Tube <i>Ryan R. Gaffney and Matthew T. Moyer</i>	1957
Chapter 133	Alternative Gastric Access Methods: SLiC and PTEG <i>Adrian B. Dobrowolsky and Bipan Chand</i>	1973

VOLUME 7

Chapter 134	‘Assisted’ PEG Placement <i>Salvatore Docimo, Jr. and Eric M. Pauli</i>	1983
Chapter 135	PEG and PEJ in the Post-Bariatric Surgery Patient <i>Ryan M. Juza and Ann M. Rogers</i>	1995
Chapter 136	Alternative Uses of Percutaneous Endoscopic Gastrostomy <i>Heidi J. Miller and Jeffrey M. Marks</i>	2009
Chapter 137	Postoperative Management <i>Fazia A. Mir, Douglas L. Nguyen and Matthew L. Bechtold</i>	2023
Chapter 138	Prevention of Peristomal PEG Infection <i>Iruru Maetani</i>	2039
Chapter 139	Acute Complications of PEG <i>Lava Y. Patel and Michael B. Ujiki</i>	2055
Chapter 140	Chronic Complications of PEG <i>Faris M. Murad and Jeffrey A. Blatnik</i>	2077
Chapter 141	Endoscopic Management of PEG Related Complications <i>Joshua S. Winder and Eric M. Pauli</i>	2091
Chapter 142	Gastric Bypass Surgery and the Skin <i>Katherine Fiala and Ryan Batson</i>	2103

Chapter 143	Treating the Obese Patient with Type 2 Diabetes Post-Bariatric Surgery <i>Steven K. Malin, Jennifer L. Kirby and Peter T. Hallowell</i>	2119
Chapter 144	Gastrointestinal Hormones and Roux-en-Y Gastric Bypass <i>Deniz Atalayer</i>	2139
Chapter 145	Bariatric Surgery Alters Gut Metabolism: Role in Obesity and Type 2 Diabetes Resolution <i>Steven K. Malin</i>	2173
Chapter 146	CT Scan and 3D Applications for Hip Surgery <i>T. Robba, D. Molino, D. Martorano and A. Borre</i>	2189
Chapter 147	3D Fluoroscopy and Its Applications in Hip Surgery <i>Matteo Giachino, Alessandro Aprato, Claudio Degiorgis, Luigi Conforti, Giuseppe Massazza and Alessandro Massè</i>	2211
Chapter 148	MRI and 3D Applications for Hip Surgery <i>M. Busso, M. Falco, E. Shaipi, G. Gallo, P. Arnoffi and A. Veltri</i>	2227
Chapter 149	A Virtual Model in Hip Preserving Surgery <i>Paolo Di Benedetto, Michele Mario Buttironi and Araldo Causero</i>	2249
Chapter 150	The Limits and Future of Collision Models <i>Alessandro Aprato, Filippo Palmesino, Luca Ulrich, Enrico Vezzetti, Matteo Giachino and Alessandro Massè</i>	2267
Chapter 151	3D Customizing in Complex Primary Hip Replacement <i>Alessandro Aprato, Simone De Vivo, Francesco Marra, Alberto Nicodemo, Alessandro Bistolfi and Alessandro Massè</i>	2275
Chapter 152	3D Customizing in Revision Hip Replacement <i>A. Aprato, A. D'Amelio, F. Marra, M. M. Favuto, D. Mellano and A. Massè</i>	2293

VOLUME 8

Chapter 153	3D Customizing in Oncologic Hip and Pelvic Surgery <i>Michele Boffano, Pietro Pellegrino, Nicola Ratto and Raimondo Piana</i>	2311
Chapter 154	The Role of Surgical Resection in Hepatocellular Carcinoma: Anatomic versus Parenchyma-Sparing Resection and Their Oncological Outcomes <i>Simone Famularo, Alessandro Giani, Fabio Uggeri, Cristina Ciulli, Luca Nespoli, Giulia Lo Bianco, Luca Arzuffi, Luca Gianotti and Fabrizio Romano</i>	2333

Chapter 155	Laparoscopic Liver Resection for Hepatocellular Carcinoma Patients: Indications and Benefits <i>Zenichi Morise</i>	2363
Chapter 156	Post-Craniotomy Temporomandibular Dysfunction: Pathophysiology, Diagnosis and Treatment <i>Thiago Martinelli, Fernando Akio Maeda, Claudio Fróes de Freitas and Andre Luiz Ferreira Costa</i>	2379
Chapter 157	Medical and Surgical Advances in Bronchoscopy <i>Jack A. Kastelik, Mahmoud Loubani, Kate Dixon and Keyvan Moghissi</i>	2389
Chapter 158	Canine Fossa Puncture for the Management of Maxillary Sinusitis <i>Federico Sireci, Francesco Martines, Francesca De Bernardi, Salvatore Poma, Francesco Dispenza, Bruno Galletti, Francesco Galletti and Frank Rikki Canevari</i>	2403
Chapter 159	Complications and Their Management in Endoscopic Sinus Surgery (ESS) <i>Federico Sireci, Francesco Martines, Pietro Salvago, Claudio Sbacchi, Vincenzo Immordino, Francesco Galletti, Bruno Galletti, Giovanni Cimino, Francesco Dispenza and Frank Rikki Canevari</i>	2409
Chapter 160	Surgical Corridors in the Transphenoidal Skull Base Surgery <i>Federico Sireci, Giulia Danè, Francesco Martines, Francesco Dispenza, Francesco Galletti, Giorgio Peretti, Matteo Vitali and Frank Rikki Canevari</i>	2419
Chapter 161	The Role of Endoscopic Sinus Surgery in Pediatric Patients with Cystic Fibrosis <i>Marco Berlucchi, Vittorio Rampinelli, Marco Ferrari, Piercarlo Poli, Luigi Fomasi, Silvana Timpano and Rita Padoan</i>	2427
Chapter 162	Postoperative Pancreatic Fistula Following Distal Pancreatectomy <i>Jennifer L. Olson and Richard J. Bold</i>	2441
Chapter 163	Mininvasive Surgical Approach in Endoscopic Sinus Surgery (ESS) <i>Federico Sireci, Francesco Galletti and Frank Rikki Canevari</i>	2455
Chapter 164	Powered Adenoidectomy <i>Max M. April</i>	2461
Chapter 165	Intracapsular Tonsillectomy: My Surgical Approach (Max M. April, MD, FAAP, FACS) <i>Max M. April</i>	2471
Chapter 166	Intracapsular Tonsillectomy: My Surgical Approach (Robert F. Ward, MD, FACS) <i>Robert F. Ward</i>	2483

Chapter 167	Intracapsular Tonsillectomy: My Surgical Approach (John P. Bent, MD) <i>John P. Bent</i>	2487
Chapter 168	Extracapsular Tonsillectomy in 2017 <i>Lyuba Gitman and Nira A. Goldstein</i>	2493
Chapter 169	Coblation Intracapsular Tonsillectomy <i>Sophie Shay and Nina L. Shapiro</i>	2513
Chapter 170	The Results of Intracapsular vs. Extracapsular Tonsillectomy <i>Benjamin J. Rubinstein and Craig S. Derkay</i>	2519
Chapter 171	The Management of Post-Tonsillectomy Pain in Children <i>David E. Tunkel and Grace X. Tan</i>	2529
Chapter 172	Conclusion and Future Questions <i>Max M. April</i>	2543
Chapter 173	DIEP Flap Breast Reconstruction: Technical Tips to Optimize Outcomes and Avoid Complications <i>Koichi Tomita and Kenji Yano</i>	2551
Chapter 174	Effect of Radiotherapy on Implant-Based Immediate Breast Reconstruction with or without Acellular Collagen Matrix: Potential Strategies to Improve Outcome <i>Baek Kim and Rajgopal Achuthan</i>	2565
Chapter 175	Patient Satisfaction Following Autologous or Heterologous Breast Reconstruction <i>Laura Sita-Alb, Laura Duta and Lucian Fodor</i>	2583
Chapter 176	What Comes after a Free Flap Failure for Breast Reconstruction? <i>Lucian Fodor, Raluca Sobec, Laura Sita and Dragos Zamfirescu</i>	2607
Chapter 177	Reconstruction of the Nipple-Areolar Complex <i>Dragos Zamfirescu, Lucian Fodor, Matei Iordache and Andreea Bularda</i>	2615
Chapter 178	Dealing with Complications after Free Flap Breast Reconstruction <i>Raluca Sobec, Ioana Tichil and Lucian Fodor</i>	2635

VOLUME 9

Chapter 179	Managing Complications in Free-Flap Breast Reconstruction <i>Gordon K. Lee, Jarom N. Gilstrap and Jennifer E. Cheesborough</i>	2649
Chapter 180	The Effect of Sleeve Gastrectomy on Metabolic Comorbidities <i>Jaime Ruiz-Tovar and Carolina Llaveró</i>	2677
Chapter 181	The Left-Handed Sleeve Gastrectomy: The Technique to Avoid Postoperative Gastric Stenosis or Gastric Twist <i>Pierre Blanc and Christophe Breton</i>	2683

Chapter 182	Weight Regain Following Sleeve Gastrectomy <i>Melanie Lauti, Andrew G. Hill and Andrew D. MacCormick</i>	2689
Chapter 183	The Utilisation of Enhanced Recovery after Surgery Programmes in Sleeve Gastrectomy <i>Daniel P. Lemanu, Andrew G. Hill and Andrew D. MacCormick</i>	2713
Chapter 184	Laparoscopic Duodenojejunal Bypass with Sleeve Gastrectomy <i>Chih-Kun Huang, Michelle Bernadette C. Lim-Loo, Thakoon Poonthananiwatkul, Vivek Kulkarni and Abhishek Katakwar</i>	2729
Chapter 185	Laparoscopic Sleeve Gastrectomy: Paying Attention to the Detail <i>F. Frattini, M. Lavazza, V. Quintodei, R. Delpini, F. Martignoni, A. Bacuzzi, E. Piantanida, S. Rausei, L. Boni and G. Dionigi</i>	2749
Chapter 186	Laparoscopic Experimental Surgery Models <i>Natalie Bath, Demetrius Litwin and Paulo N. Martins</i>	2761
Chapter 187	Experimental Models of Sepsis <i>Norbert Nemeth, Mihai Oltean and Bela Fulesdi</i>	2795
Chapter 188	Bariatric Experimental Surgery Models <i>Osman Bilgin Gulcicek</i>	2831
Chapter 189	Animal Models of Heart Failure <i>Mouer Wang</i>	2839
Chapter 190	Hepatopancreatobiliary Surgery Experimental Models <i>Paulo N. Martins, Natalie Bath and Adel Bozorgzadeh</i>	2865
Chapter 191	Animal Models of Acute Graft-Versus-Host and Host-Versus-Graft Responses and Disease <i>Abraham Matar and Raimon Duran-Struuck</i>	2915
Chapter 192	Microfluidic Devices and Micro-Dissected Tissue to Predict Therapeutic Response in Patients with Prostate Cancer <i>Robin Guay-Lord, Muhammad Abdul Lateef, Kayla Simeone, Benjamin Péant, Jennifer Kendall-Dupont, Anne-Marie Mes-Masson, Thomas Gervais and Fred Saad</i>	2939
Chapter 193	Of Mice and Rats: Animal Models for Use in Laparoscopy and Laparotomy with Human Ovarian Cancer Cell Line Intraperitoneal Xenografts <i>Philippe Sauthier, Anne-Marie Mes-Masson, Louise Champoux, Michèle Bally and Diane M. Provencher</i>	2967

VOLUME 10

Chapter 194	Organ Bioengineering through Decellularization and Recellularization Approaches <i>Maria Jaramillo and Basak E. Uygun</i>	2983
--------------------	--	-------------

Chapter 195	Wound Healing and Scarring <i>A. Samandar Dowlatshahi</i>	3009
Chapter 196	Organ Preservation <i>Cheng Yang, Jiawei Li and Ruiming Rong</i>	3023
Chapter 197	Machine Organ Preservation <i>Hazel L. Marecki, Isabel Brüggewirth and Paulo N. Martins</i>	3043
Chapter 198	Microcirculation <i>Norbert Nemeth and Andrea Szabo</i>	3073
Chapter 199	Experimental Gene Therapy Using Naked DNA <i>Eiji Kobayashi</i>	3115
Chapter 200	Robotic Surgery in Experimental Medicine <i>Sandra S. Y. Kim, David Ian Harriman and Christopher Ngan</i>	3129
Chapter 201	History, Development and the Importance of Experimental Surgery <i>Huifang Chen and Pierre Daloze</i>	3159
Chapter 202	The Discovery, Development and Patent Protection of New Drugs in Experimental and Clinical Research <i>Anlun Ma</i>	3201
Chapter 203	Ethical, Legal and Educational Issues in Experimental Surgery <i>Kupa Bilolo</i>	3237
Chapter 204	Veterinary Care and Management of Rodent and Large Animal Models in Transplantation Research <i>Patrick Lester, James Marx, Portia S. Allen, Bram V. Lutton and Raimon Duran-Struuck</i>	3259
Chapter 205	Pre-Operative and Postoperative Care in Experimental Surgery <i>Yanxin Hu</i>	3303

VOLUME 11

Chapter 206	Fluid, Electrolytes, and Acid-Base Balance in Experimental Surgery <i>Kupa Bilolo</i>	3313
Chapter 207	Imagery Techniques in Experimental Surgery <i>Junzheng Peng and Huifang Chen</i>	3337
Chapter 208	Telemetry Applications in Experimental Animals for Studying Human Diseases <i>Junzheng Peng and Huifang Chen</i>	3375
Chapter 209	Small Animals as Experimental Models <i>Rebekah Wilson, Adrien Kissenpfennig and James McDaid</i>	3413
Chapter 210	Large and Translational Animal Models in Experimental Surgery <i>Kupa Bilolo</i>	3427

Chapter 211	Cardiovascular Biomechanical Models <i>Ethan Kung</i>	3449
Chapter 212	Isolated Kidney Perfusion Models <i>Isabel M. A. Brüggewirth, Henri G. D. Leuvenink and Paulo N. Martins</i>	3479
Chapter 213	Isolated Liver Perfusion Systems <i>Isabel Brüggewirth, Hazel Marecki and Paulo N. Martins</i>	3509
Chapter 214	Experimental Models of Cartilage Repair <i>Jakub Zafar Qazi, Huifang Chen and Muhammad Zafarullah</i>	3537
Chapter 215	Experimental Models of Fracture Repair <i>Jakub Zafar Qazi, Huifang Chen and Muhammad Zafarullah</i>	3557
Chapter 216	Experimental Solid Organ Transplantation in Small Animals <i>Hao Dun</i>	3583
Chapter 217	Large Animal Models in Organ Transplantation <i>Babak Movahedi, Maria Lucia Madariaga, Sebastian Michel, Adel Bozorgzadeh and Paulo N. Martins</i>	3611
VOLUME 12		
Chapter 218	Experimental Composite Tissues and Soft Tissues Transplantation <i>Hao Wang</i>	3647
Chapter 219	Ischemia-Reperfusion Injury Animal Models <i>Junzheng Peng and Huifang Chen</i>	3665
Chapter 220	Encapsulated Islet Transplantation: From Allogeneic to Xenogeneic Transplantation <i>Kun Ho Yoon, Eun Young Lee, Jun-Seop Shin, Byoung-Hoon Min, Jong-Min Kim and Chung-Gyu Park</i>	3721
Chapter 221	Hepatocyte Transplantation <i>Nalu Navarro Alvarez and Paulo Martins</i>	3745
Chapter 222	Preclinical Models of Decompressive Craniectomy: Lessons from Experimental Traumatic Brain Injury and Other Disease Models <i>E. G. Hayman, M. J. Kole and J. M. Simard</i>	3765
Chapter 223	Impaired Cerebral Energy Metabolism Following Traumatic Brain Injury Contributes to Poor Outcomes and Limits the Effectiveness of Decompressive Craniectomy <i>Courtney L. Robertson and Gary M. Fiskum</i>	3781
Chapter 224	Multimodal Monitoring in Decompressive Craniectomy for Traumatic Brain Injury and Stroke <i>Masoom Desai, Corey Lewis and Neeraj Badjatia</i>	3799

Chapter 225	Decompressive Craniectomy: The Effects on Neurochemistry and Brain Oxygen Delivery <i>Anna Teresa Mazzeo, Ashley Ralston, Deepak Gupta and Ross Bullock</i>	3835
Chapter 226	Medical Management of Intracranial Hypertension and Indications for Secondary Decompressive Craniectomy <i>G. Schwartzbauer and D. Stein</i>	3851
Chapter 227	Preoperative and Postoperative Nursing Care of Patients Undergoing Decompressive Craniectomy <i>Karen A. McQuillan and Tya Schoppe</i>	3875
Chapter 228	Decompressive Laparotomy to Treat Intracranial Hypertension and Multiple Compartment Syndrome <i>Margaret H. Lauerman and Thomas M. Scalea</i>	3917
Chapter 229	Decompressive Craniectomy in Ischemic Stroke <i>Matthew Jaffa, Carolyn A. Cronin and Barney J. Stern</i>	3931
Chapter 230	Decompressive Craniectomy in Diffuse Injury: Interpretation and Implications of the International DECRA Randomized Trial <i>D. J. Cooper, A. Udy, A. Nichol, J. V. Rosenfeld and M. Hunn</i>	3949
Chapter 231	Decompressive Craniectomy for Refractory Posttraumatic Intracranial Hypertension: Interpretation and Implications of the International RESCUEicp Randomized Trial <i>Tamara Tajsic, Angelos G. Koliass, Hadie Adams, Ivan Timofeev, David K. Menon and Peter J. Hutchinson</i>	3957
Chapter 232	Outcome Following Decompressive Craniectomy for Managing High Intracranial Pressure in Traumatic Brain Injury Patients: A Systematic Review <i>Juan Sahuquillo and Jane A. Dennis</i>	3967

VOLUME 13

Chapter 233	Decompressive Craniectomy in Pediatric TBI <i>David S. Hersh and Mari L. A. Groves</i>	3991
Chapter 234	Early Decompressive Craniectomy for Blast and Penetrating Brain Injury in War: Lessons for Civilian Surgeons <i>Jeffrey V. Rosenfeld, Randy S. Bell and Rocco Armonda</i>	4011
Chapter 235	Decompressive Craniectomy in Casualties from OIF and OEF: Management after Evacuation from the War Zone <i>Chris J. Neal, Randy S. Bell, Nicholas Szuflita and Rocco Armonda</i>	4033

Chapter 236	Guidelines for the Management of Severe Traumatic Brain Injury: Recommendations from the 2017 Fourth Edition <i>Kevin Kwan, Jamie S. Ullman, Julia Schneider, Gregory W. J. Hawryluk, Annette Totten and Jamshid Ghajar</i>	4045
Chapter 237	Decompressive Craniectomy: Surgical Indications in Developed versus Developing Countries <i>Franco Servadei, Corrado Iaccarino, Edoardo Picetti, Davide Nasi and Stephen Honeybul</i>	4055
Chapter 238	Timing and Technique of Cranioplasty <i>Gabriel F. Santiago, Judy Huang and Chad R. Gordon</i>	4071
Chapter 239	Complications of Decompressive Craniectomy <i>M. J. Kole, D. S. Hersh and G. Schwartzbauer</i>	4081
Chapter 240	Decompressive Craniectomy: Prognosis and Communication with Patient Families <i>O. Ugochukwu, D. Stein and S. Honeybul</i>	4091
Chapter 241	Ethical Considerations in Decompressive Craniectomy <i>Stephen Honeybul, Franco Servadei, Kwok Ming Ho, Luca Longhi and Grant Gillett</i>	4107
Chapter 242	The Prognostic Value of Traumatic Brainstem Injury on Magnetic Resonance Imaging: A Systematic Review <i>B. Aarabi, A. Wessell, N. Pratt, T. Chryssikos, M. Scarboro, C. Diaz Lomangino and C. Aresco</i>	4119
Chapter 243	Robotic Portal Lung Resection <i>Roman V. Petro, Charles T. Bakhos and Abbas E. Abbas</i>	4141
Chapter 244	Robotic-Assisted Mediastinal Mass Resection <i>Wissam Raad and Faiz Bhora</i>	4153
Chapter 245	Robotic Assisted Minimally Invasive Esophagectomy for Esophageal Cancer <i>Matthew C. Black, James D. Luketich and Inderpal S. Sarkaria</i>	4159
Chapter 246	Fundamental Approaches and Challenges to Benign Esophageal Robotic Surgery <i>Caitlin Wahl and John F. Lazar</i>	4171
Chapter 247	Robotic Mitral Valve Replacement and Repair <i>T. Sloane Guy, Lucas B. Ohmes and Ahmed A. Abouarab</i>	4187
Chapter 248	Robotic Coronary Revascularization <i>Philip Erwin, Sharon Ben-Or and Eric J. Lehr</i>	4201
Chapter 249	Robotic Approaches for Rectal Cancer <i>Kevin T. Behm and David W. Larson</i>	4219

Chapter 250	Robotic-Assisted Abdominal Wall Hernia Repair <i>Paul A. R. Del Prado and James G. Bittner, IV</i>	4237
Chapter 251	Robotic Hepatobiliary and Pancreatic Surgery <i>Sushruta S. Nagarkatti and John B. Martinie</i>	4261
Chapter 252	Robotic-Assisted Bariatric Surgery <i>Matthew Sharbaugh and Christopher You</i>	4291

VOLUME 14

Chapter 253	Robotic Urologic Surgery for Benign Disease <i>Aryeh Keehn and Daniel Eun</i>	4317
Chapter 254	Robotic Surgery for Urologic Malignancies <i>Jay D. Raman</i>	4345
Chapter 255	Applications of Robotic-Assisted Surgery in Urogynecology <i>Sarah A. Huber and Patrick J. Culligan</i>	4367
Chapter 256	Robotic Surgery: Clinical Perceptions, Approaches, and Challenges in Gynecologic Oncology <i>Tommaso Grassi, Valentina Zanfagnin, Stephanie R. DeJong, Jvan Casarin and Andrea Mariani</i>	4397
Chapter 257	Transoral Robotic Surgery: Treatment of Head and Neck Disease <i>Changxing Liu, Mark Swanson and Niels Kokot</i>	4447
Chapter 258	Robotic Surgery: Evolution, Challenges and the Future <i>Richard S. Lazzaro, Byron Patton, Landon Guntman and Faiz Bhora</i>	4463
Chapter 259	Robotic Surgery in Benign Gynecology <i>Yonghee K. Cho and Gerald Harkins</i>	4471
Chapter 260	Antibiotic Prophylaxis in Bariatric Surgery <i>Andrés García-Marín and Mercedes Pérez-López</i>	4499
Chapter 261	Thromboembolic Prophylaxis <i>Jaime Ruiz-Tovar and Carolina Llaveró</i>	4505
Chapter 262	Antiemetic Prophylaxis <i>Esther García Villabona, Carmen Vallejo Lantero and Graciela García Villabona</i>	4511
Chapter 263	Nutritional Prophylaxis: Weight Loss for the Reduction of Surgical Risk <i>Irene Portero Larraqueta</i>	4527
Chapter 264	Prophylaxis of Postoperative Cholelithiasis <i>Dennis Cesar Levano-Linares, Patricia Sanchez-Salcedo, Gustavo Díaz García, David Alías Jimenez, Manuel Durán Poveda and Jaime Ruíz-Tovar</i>	4537

Chapter 265	Prophylactic Measures to Reduce Staple Line Leaks and Bleeding <i>Irene Ortega-Vázquez</i>	4545
Chapter 266	Postoperative Ileus Prophylaxis: Enhanced Recovery after Surgery (ERAS) <i>Pablo Royo-Dachary and Helen Almeida-Ponce</i>	4555
Chapter 267	Prophylaxis of Stress Ulcers, Anastomotic Ulcers and Gastroesophageal Reflux Disease <i>Pablo Priego</i>	4569
Chapter 268	Postoperative Pain Prophylaxis and Management <i>Carmen Vallejo Lantero and Esther García Villabona</i>	4587
Chapter 269	The Use of Prophylactic Mesh in Open and Laparoscopic Bariatric Surgery <i>Montiel Jiménez-Fuertes</i>	4595
Chapter 270	Prophylaxis of Internal Hernias <i>Manuel Ferrer-Márquez and Maria José Solvas-Salmerón</i>	4603
Chapter 271	Epidemiology of Surgical Site Infection <i>Pablo Priego</i>	4611
Chapter 272	Adequate Nutritional Support for the Prophylaxis of Surgical Site Infection <i>Andrei Sarmiento, Grace Amesquita and Ramiro Carbajal</i>	4623
Chapter 273	Preoperative Bath and Shave <i>Cristina Bernabeu Herraiz and Lorena Rodríguez Cazalla</i>	4633
Chapter 274	Mechanical Bowel Preparation <i>Andrés García Marín and Mercedes Pérez López</i>	4637
Chapter 275	Antibiotic Prophylaxis <i>Noel Rojas-Bonet and Maria del Mar García-Navarro</i>	4641
Chapter 276	Hands and Skin Preparation <i>Lorena Rodríguez Cazalla and Cristina Bernabeu Herraiz</i>	4647

VOLUME 15

Chapter 277	Hyperoxygenation, Hypothermia Prevention, Normoglycemia and Normovolemia <i>Esther García Villabona and Carmen Vallejo Lantero</i>	4653
Chapter 278	Adhesives and Wound Protectors <i>Dennis César Lévano-Linares and Patricia Sanchez-Salcedo</i>	4663
Chapter 279	Wound Irrigation <i>Gilberto González Ramírez</i>	4671
Chapter 280	Topical Intraperitoneal Irrigation <i>Jaime Ruiz-Tovar and Carolina Llaveró</i>	4687

Chapter 281	Prophylactic Vacuum Therapy <i>Montiel Jiménez-Fuertes</i>	4693
Chapter 282	Antimicrobial Sutures <i>Jaime Ruiz-Tovar and Carolina Llaveró</i>	4701
Chapter 283	Wound Cover: Topical Antibiotics or Antiseptics <i>Helen Almeida Ponce and Pablo Royo Dachary</i>	4709
Chapter 284	Clinical Examination, Imaging and Basic Surgical Techniques <i>Peter Stefanic</i>	4721

Chapter 286	Descending and Thoracoabdominal Aorta <i>Tomáš Toporcer</i>	4781
Chapter 287	Abdominal Aorta, Iliac, and Splanchnic Arteries <i>Vladimir Sihotsky</i>	4811
Chapter 288	Carotid and Vertebral Arteries <i>Vladimir Katuch</i>	4849
Chapter 289	Peripheral Arterial Disease: Upper Extremity Artery Disease, Lower Extremity Artery Disease, Acute Limb Ischemia <i>Mária Kubíková</i>	4871
Chapter 290	Vascular Trauma <i>Ivan Kopolovets</i>	4911
Chapter 291	Vascular Access for Hemodialysis, Venous Insufficiency, and Its Treatment <i>Norbert Torma</i>	4933

VOLUME 16

Chapter 292	Complications and Recovery in Vascular Surgery <i>Peter Berek</i>	4975
Chapter 293	Laparoscopic Sleeve Gastrectomy <i>Pablo Priego</i>	5015
Chapter 294	Laparoscopic Adjustable Gastric Banding <i>Marta Cuadrado Ayuso, Rocio Franco Herrera and Jesús Lago Oliver</i>	5045
Chapter 295	Laparoscopic Nissen-Sleeve Gastrectomy <i>Alejandro García Muñoz-Najar, Camilo Castellon Pavon, Manuel Duran and Jaime Ruiz-Tovar</i>	5063

Chapter 296	Laparoscopic Roux-en Y Gastric Bypass with Linear Stapled Anastomoses <i>Camilo J. Castellón Pavón, Alejandro García Muñoz-Najar, Jaime Ruiz-Tovar and Manuel Durán Poveda</i>	5085
Chapter 297	Laparoscopic Roux-en-Y Gastric Bypass: Circular Anastomosis <i>Maria Posada, Gabriel Salcedo, Jose Ramon Torres and Peter Vorwald</i>	5101
Chapter 298	Laparoscopic Roux-en-Y Gastric Bypass with Hand-Sewn Gastrojejunal Anastomosis <i>Alejandro Garcia Muñoz-Najar, Manuel Medina Garcia, Leire Zarain Obrador and Manuel Duran Poveda</i>	5141
Chapter 299	Laparoscopic Mini-Gastric Bypass <i>Dennis Cesar Levano-Linares, Patricia Sanchez Salcedo, Irene Grao, Manuel Duran Poveda, David Alías Jiménez and Jaime Ruiz-Tovar</i>	5163
Chapter 300	Laparoscopic One-Anastomosis Gastric Bypass (OAGB-BAGUA) <i>Jaime Ruiz-Tovar, Alejandro Garcia, Camilo Castellon, Manuel Duran and Carolina Llaverro</i>	5179
Chapter 301	Laparoscopic Duodenal Switch <i>Nieves Perez-Climent, Carlos Serra, Miriam Ortin, Rafael Bou and Aniceto Baltasar</i>	5203
Chapter 302	Laparoscopic Biliopancreatic Diversion <i>Alberto Pagan</i>	5229
Chapter 303	Introduction to NAFLD and NASH: Etiopathogenesis <i>Soledad García-Gómez-Heras, Julio Paredes-González and Raquel Franco-Rodríguez</i>	5247
Chapter 304	Epidemiology and Relevance of NASH in Patients with Morbid Obesity <i>Leire Zarain-Obrador and Manuel Duran-Poveda</i>	5265
Chapter 305	Fatty Liver Development: Imbalance between Acquisition and Removal of Lipids <i>Lorea Zubiaga</i>	5273
Chapter 306	Histopathology of NAFLD and NASH <i>Soledad García-Gómez-Heras</i>	5287

VOLUME 17

Chapter 307	Liver Biopsy as the “Gold Standard” in NASH Diagnosis <i>Soledad García-Gómez-Heras, Julio Paredes-González and Raquel Franco-Rodríguez</i>	5301
--------------------	--	-------------

Chapter 308	Conventional Imaging Tests for the Evaluation of NASH <i>Luis Tomás Ocaña Wilhelmi, Bruno Ramos Molina and Enrique Glückmann Maldonado</i>	5331
Chapter 309	MR Spectroscopy and Quantification of Intrahepatocitary Lipid Content <i>Jaime Ruiz-Tovar and Carolina Llaveró</i>	5343
Chapter 310	Biochemical Markers <i>Soledad García-Gómez-Heras</i>	5351
Chapter 311	Evolution of Liver Steatosis after Sleeve Gastrectomy <i>Ramiro Carbajal Nicho, Andrei Sarmiento Alarcón, Nestor Palacios Bran and Jorge Orrego Peche</i>	5357
Chapter 312	Liver Steatosis and Roux-en-Y Gastric Bypass (RYGB) <i>Luciano Deluca, Liliana Parasporo, Patricio Cal and Ezequiel Fernández</i>	5365
Chapter 313	Liver Steatosis Regression after One Anastomosis Gastric Bypass <i>Luciano Antozzi, Miguel Angel Carbajo, Priscila Antozzi and Carlos Martin Esquivel</i>	5373
Chapter 314	SADI-S: Characteristics and Results of a Novel Bariatric Surgery Technique. The Role in NAFLD and NASH <i>Esteban Martin-Antona, Oscar Cano-Valderrama, Ester Martin Garcia-Almenta, Miguel Josa and Antonio J. Torres</i>	5389
Chapter 315	Simultaneous Liver Transplantation and Bariatric Surgery <i>David Calatayud, Eva María Montalvá, Javier Maupoey, Andrea Boscá and Rafael López-Andújar</i>	5399
Chapter 316	Non-Surgical Treatment of NASH: The Other Options <i>Raúl Bernal-Reyes and Daniel Bernal-Serrano</i>	5419
Chapter 317	The Use of Groin Flap for Upper Extremity Coverage in Electrical Burn Patients: Evidence-Based Case Reports <i>Nathania Pudya, Aditya Warhana and Erythrina Permatasari</i>	5431
Chapter 318	Autopsy of Aortic Dissection after TEVAR Installation: A Case Report <i>Yuli Budiningsih and Insil P. Hariyani</i>	5441
Chapter 319	Rare Occurrence of Secondary Extracranial Sinonasal Meningioma: A Case Report <i>Renindra Ananda Aman, Adhitya Syahada, Aryandhito Widhi Nugroho, David Tandian, Samsul Ashari, Syaiful Ichwan and Setyo Widi Nugroho</i>	5449

Chapter 320	Thoracic Epidural Analgesia in a Critically Ill Patient with Acute Pancreatitis <i>Dita Aditianingsih, Raden Besthadi Sukmono, Oryza Eureka, Willy Yant Kartolo and Erika Sasha Adiwongso</i>	5457
Chapter 321	Preoperative Therapeutic Plasma Exchange with Hypofibrinogenemia Complication in ABO-Incompatible Living Donor Kidney Transplantation <i>Dita Aditianingsih, Rudyanto Soedono, Endang Susalit, Willy Yant Kartolo and Erika Sasha Adiwongso</i>	5463
Chapter 322	Symmetrical Bilateral Keystone Perforator Island Flaps for Vulvar Reconstruction after Oncological Resection: A Case Report <i>Indri Aulia, Chaula Luthfia Sukasah and Eva Chintia Yessica</i>	5471
Chapter 323	Reconstruction of Auricle after Wide Excision of Giant Multiple Congenital Melanocytic Nevus of the Ear: A Rare Case Report <i>Dini Widiarni Widodo and Ferucha Moulanda</i>	5475
Chapter 324	Deviated Nose in a Patient with Parry–Romberg Syndrome: A Case Report <i>Mirta Hedyati Reksodiputro, Dewi Puspito Sari, Iris Rengganis, Endi Novianto and Dini W Widodo</i>	5481
Chapter 325	Use of Nasolabial and Nasal Septal Flaps for Unilateral Lower-Third Nasal Defects <i>Mirta H. Reksodiputro, Satria Dipo Putra Asmoro, Dini W. Widodo and Trimartani Koento</i>	5487
Chapter 326	Supernumerary Nostril: A Rare Congenital Anomaly <i>Dini Widiarni Widodo and Rindy Yunita Pratamisiwi</i>	5493
Chapter 327	Objective Measures in Functional Septorhinoplasty: Two Case Reports of Nasal Form and Nasal Valve Reconstruction <i>Trimartani Koento, Tiara Melati and Mirta H. Reksodiputro</i>	5499
Chapter 328	The Role of Voice Therapy in Reducing Voice-Related Symptoms in Laryngopharyngeal Reflux Evaluated by Reflux Symptom Index, Voice Handicap Index, and Laryngovideostroboscopy <i>Elvie Zulka Kautzia Rachmawati, Yonian Gentilis, Rahmanofa Yunizaf, Susyana Tamin, Fauziah Fardizza and Luh Karunia Wahyuni</i>	5505
Chapter 329	Maxillary Fibrous Dysplasia Reconstruction after Maxillectomy <i>Dini Widiarni Widodo and Razki Yorivan</i>	5515
Chapter 330	Cleft Palate with Velopharyngeal Insufficiency: A Case Report <i>Mirta H. Reksodiputro, Shally Adhina Putri, Dini W. Widodo and Trimartani Koento</i>	5537
Chapter 331	Tongue Edema after Palatoplasty: A Case Report <i>Rahendra, Pradini</i>	5543

Chapter 332	Non-Syndromic Unilateral Tessier No. 3 Facial Cleft: A Rare Congenital Disease <i>Mirta H. Reksodiputro, Tara C. Mariska, Dini W. Widodo and Trimartani Koento</i>	5549
Chapter 333	Outcomes of Resection Arthrodesis for Knee Malignancies <i>Yogi Prabowo, Afif Alhadi and Adisa Yusuf Reksoprodjo</i>	5557
Chapter 334	Total Sacrectomy and Spinopelvic Reconstruction of Sacrococcygeal Chordoma <i>Yogi Prabowo, Afif Alhadi and Rizky Priambodo Wisnubaroto</i>	5563
Chapter 335	Low Back and Leg Pain Induced by Dural Scar Formation after Laminectomy for Lumbar Canal Stenosis: Case Report and Literature Review <i>Ahmad Jabir Rahyussalim, Aria Adhitya, Tri Kurniawati and Khairul Hukmi</i>	5571
Chapter 336	Functional and Radiological Outcomes in Patients with Spondylitis Tuberculosis and Kyphotic Deformity Treated Using a Two-Stage Correction Procedure: A Case Series <i>Ifran Saleh and Auliya Akbar</i>	5577
Chapter 337	Management of Neglected Conus Medullaris Syndrome with Lumbar Canal Stenosis <i>Ahmad Jabir Rahyussalim, Sammy Saleh Alhuraiby, Tri Kurniawati and Khairul Hukmi</i>	5585
Chapter 338	Anterior Innominate Osteotomy for Closure of Neglected Bladder Exstrophy: A Report of Two Cases and a Brief Review of the Literature <i>Aryadi Kurniawan and Andi Praja Wira Yudha Luthfi</i>	5593
Chapter 339	Successful Treatment of Fracture at the Base of the Proximal Phalanx Using Extra-Articular Percutaneous K-Wiring with the Consideration of Safe Portals: A Case Report <i>Wahyu Widodo and Andi Praja Wira Yudha Luthfi</i>	5601
Chapter 340	The Role of Acupuncture in a Breast Cancer Patient with Cancer-Induced Bone Pain <i>Kemas Abdurrohman, Irma Nareswari and Diana Oei</i>	5609
Chapter 341	A Rare Case of CD8-Negative Monomorphic Epitheliotropic Intestinal T-Cell Lymphoma <i>Agnes Stephanie Harahap, Lydia Kencana, Maria Francisca Ham, Budiana Tanurahardja and Endang S. R. Hardjolukito</i>	5617
Chapter 342	A Rare Case of Clear Cell Papillary Renal Cell Carcinoma <i>Fili Sufangga and Budiana Tanurahardja</i>	5631

VOLUME 18

Chapter 343	Rare Case of Myelolipomatous Metaplasia within an Adrenocortical Adenoma <i>Monik Ediana Miranda, Maria Francisca Ham, Agnes Stephani Harahap and Benyamin Makes</i>	5641
Chapter 344	Chronic Myeloid Leukemia in a BCR-ABL1-Positive Patient with Pancytopenia and Excessive Fibrosis <i>Dian Sari Oethia Vathonati and Agnes Stephanie Harahap</i>	5653
Chapter 345	Clear Cell Chondrosarcoma: A Case Report <i>Ros Nirmawati, Evelina Kodrat and Errol Untung Hutagalung</i>	5665
Chapter 346	Hürthle Cell Carcinoma: A Rare Case with Unique Morphological Features <i>Familia Bella Rahadiati, Agnes Stephanie Harahap and Maria Fransiska Ham</i>	5675
Chapter 347	Invasive Breast Carcinoma Mimicking Secretory Carcinoma: A Case Report <i>Patricia Fransisca Julianty, Primariadewi Rustamadji and Hartono Tjahjadi</i>	5689
Chapter 348	Langerhans Cell Histiocytosis with Unusual Nodular Pattern <i>Imelda Setiana Silitonga and Endang Sri Roostini Hardjolukito</i>	5701
Chapter 349	Pitfalls in the Histopathological Diagnosis of Sclerosing Rhabdomyosarcoma <i>Fetisari Kurniawan, Nurjati Chairani Siregar, Ludi Dhyani Rahmartani, Marcel Prasetyo and Kshetra Rinaldhy</i>	5711
Chapter 350	Primary Malignant Giant Cell Tumor of Proximal Right Tibia: A Rare Case Report <i>Mirna Albertina Wijaja, Nurjati Chairani Siregar, Evelina Kodrat, Yogi Prabowo and Thariqah Salamah</i>	5721
Chapter 351	Secondary Malignant Giant Cell Tumor of the Bone: A Case Report and Rare Experience <i>Fadhline Muharmi Harahap, Nurjati Chairani Siregar, Yogi Prabowo and Thariqah Salamah</i>	5731
Chapter 352	Segmental Absence of Intestinal Musculature: Case Report of a Rare Cause of Neonatal Intestinal Obstruction <i>Ignasia Andhini Retnowulan and Nur Rahadiani</i>	5741
Chapter 353	Hemangioma-Like Vessels in the Resection Margin of Giant Hemangiomas of the Liver as a Possible Cause of Recurrence: A Case Series and Literature Review <i>Marini Stephanie, Ening Krisnuhoni, Diah Rini Handjari and Nur Rahadiani</i>	5751

Chapter 354	46, XX Ovotesticular Disorder of Sex Development, Histopathological View: Report of a Rare Case <i>Intan Nevita Oktamiya Bernanthos and Budiana Tanurahardja</i>	5757
Chapter 355	A 56-Year-Old Woman with an Elevated Parathormone Level after the Surgery for Secondary Hyperparathyroidism <i>Caglar Keskin and Mustafa Şahin</i>	5773
Chapter 356	Epilepsy Surgery and Technical Aspects of Invasive Monitoring <i>Jorge A. González-Martínez</i>	5775

Chapter 1

LIMB LENGTHENING BY COMBINED TECHNIQUE (EXTERNAL FIXATOR AND FLEXIBLE INTRAMEDULLARY NAILING): EXPERIMENTAL STUDIES

Dmitry Popkov* and Arnold Popkov

Scientific and Clinical Laboratory for Deformity Correction and Limb Lengthening.
Federal Russian State-Financed Ilizarov Scientific Center for Restorative
Traumatology and Orthopaedics, Kurgan, Russia

ABSTRACT

The experimental results of application of bioinert and bioactive intramedullary nailing in tibial lengthening in mongrels are presented in Chapter I. Basing on data of radiologic, angiographic and morphologic investigations, the advantages of combination of circular external fixation and flexible intramedullary nailing in a gradual limb lengthening are proved from the point of view of stimulation of the osteogenesis and accelerated formation of the distraction regenerate.

Keywords: combined technique of limb lengthening, experimental study

1.1. TIBIAL LENGTHENING WITH FLEXIBLE INTRAMEDULLARY INERT NAILING

Introduction

Based on our extensive experience with the Ilizarov lengthening method, we have demonstrated that one of its fundamentals is preservation of periosteum and intramedullary circulation. Furthermore, quality of the regenerate depends on the lengthening rate, which can

* Corresponding Author's Email: dpopkov@mail.ru.

be individualized [2]. Automatic high-frequency lengthening and compression of the regenerate immediately after the lengthening period provide optimal conditions for tissue regeneration, and result in significant reduction of the external fixation period [3]. Works have been done to demonstrate the prominent role of periosteum in distraction osteogenesis [4, 5]. Intramedullary nailing provides a strong elastic frame, which enhances the formation of periosteal callus. Additionally, as the two intramedullary nails do not completely fill the medullary cavity, endosteal callus formation is not inhibited. We have worked on the FIN concept to ensure compatibility with the Ilizarov method for limb lengthening. The following study conducted in dogs allows better understanding of our philosophy, and evaluating all the benefits of this combined method.

Materials and Methods

This study was conducted in 14 dogs of various breeds, aged 1 to 4 years, with the average weight of 18.8 kg. The mean length of tibia was 187 mm. The applied Ilizarov fixator consisted of two distal rings and two proximal three-quarter rings, connected by threaded rods. Both, percutaneous osteotomy of the fibula and osteoclasis of the tibia were performed in the middle third of the diaphysis. The FIN construct used two 1.5 mm nails with opposing curves (Figure 1). Both nails were sharply contoured, and their tips bent to 30–40° over a length of 2–3 mm. Their initial curves were identical, with apex located in the midsection. Both nails had blunt tips. Two slightly oblique entry holes were made with an awl in the superior portion of the proximal metaphysis. The first nail was hand pushed into the medullary canal, then across the osteoclasis and down to the distal metaphysis, as far as possible into the cancellous bone. The second nail was inserted in the same manner, on the opposite side of the bone. The final construct consisted of two nails with opposing curves positioned in the same plane. The free ends (trailing ends) of the nails were cut relatively short and bent to about 45–60° to prevent nail migration during distraction. The skin was closed in one layer. Distraction was initiated on the fifth day in all dogs (Figure 1). Duration of lengthening was 28 days. Mean distraction rate was 1 mm/day (in four steps) (Table 1).

However, as control X-rays showed extensive bone regenerate, the distraction speed had to be increased on D 8 in 4 dogs, D 15 in 3, and D 21 in 1. Early healing occurred twice in about 21 days of lengthening, and twice in about 28 days: in two cases, distraction resulted in fracture of the regenerate that had already consolidated (Figure 2), whereas in the other two cases, the newly regenerated bone was already very strong. The 28-day lengthening period was followed by the external fixation period. The external fixator was removed after 15 days (sixth week) in eight dogs and 30 days (eighth week) in four. All the dogs could bear weight right after removal of the external fixator without any limb protection.

Results were evaluated according to the radiographic appearance of the regenerate. Control X-rays were performed on a weekly basis throughout the distraction period, and thereafter, at 45 days, 60 days, and after removal of the intramedullary nails. Arteriographies were performed in some dogs after sacrifice: at D 5, 39, and 63. Additionally, bone regenerates were histologically studied.

Figure 1. Radiograph of the right tibia. Tibial lengthening by combined Ilizarov/FIN: Ilizarov fixator and intramedullary nails in place, osteoclasis of the tibia(a); X-ray taken after 21 days of lengthening(b); X-ray taken after 28 days of lengthening (end of lengthening period) (c). Note the intense and extensive periosteal reaction, and a growth zone with numerous bone trabeculae. Thirty millimeter lengthening: Complete healing achieved after 14 days of external fixation (d); external fixator removed (e); X-ray taken 15 days (D 63) after removal of the external fixator and resumption of weight bearing.

Table 1. Duration of the lengthening and external fixation

Period	Osteoclasis, Ilizarov +FIN	Distraction (lengthening)	External fixation	Removal of external fixation
Date	Day 0	Days 5-33	Days 34-49=6 dogs Days 34-63=8 dogs	Days 49=6 dogs Day 63=8 dogs

Figure 2. Healing status after 14 days of tibial lengthening using combined Ilizarov/FIN: Ilizarov fixator and two intramedullary nails in place, closed osteoclasia of the tibia (a); X-ray taken after 14 days of lengthening at a rate of 1.75 mm/day (b); X-ray taken after 21 days of lengthening, fracture of the regenerate (c).

Results

Radiological changes proved intense and extensive bone regeneration, it forced us to increase the distraction speed in some dogs. Newly formed bone was visible on radiographs after 7 days of lengthening. At this stage, the regenerate had an inhomogeneous structure with localized areas of increased bone density. Extensive periosteal reaction (21.6 mm long, 0.5–2.0 mm thick) could be noted along the bone fragments. At 2 weeks, the regenerate was well structured and filled completely the interfragmentary gap. The growth zone contained numerous bone trabeculae. Periosteal reaction was 24–26 mm long and 2–3 mm thick. The regenerate was larger than the tibia. In 15 days of fixation (D 48), the regenerate was completely consolidated in all the animals. Cortical bone was reconstructed. Continuity of three or four cortices was reestablished along the regenerate. The growth zone had disappeared. A denser periosteal reaction was noted. In 30 days of fixation (D 63), the medullary canal was already formed in three out of four dogs. No fracture or deformity occurred after removal of the external fixator because the regenerates had already consolidated, and also because the bones were protected by FIN.

After 15 days of external fixation, histology showed cortical continuity, fully interconnected cancellous trabeculae, and disappearance of the fibrous layer surrounding the new bone (Figure 3a). As a matter of fact, consolidation took place during the fixation period and lasted 2 weeks.

Thirty days after removal of the external fixator, the cortices were thicker. Remodeling of the medullary canal was under way. We were happy to note extensive tissue regeneration along the intramedullary nail (Figure 3b).

Figure 3. Histologic sections (tibia): specimen at D 49 (fixator removed), cortices were present along the regenerate and continuity was re-established. Growth zone was no longer visible (a); specimen at D 88, 25 days after removal of the external fixator, intramedullary nails were removed just before sacrifice (b). Regenerate consisted of cortical and cancellous bone tissue. The medullary canal was patent. Ossification was present along the intramedullary nails.

Figure 4. Arteriography: the medullary artery was patent (tibia-dog): Arteriography (AP and lateral) of specimen after removal of the intramedullary nails on the 6th day of the fixation period (D 39) (a); arteriography (AP and lateral) after 30 days of fixation (D 63) (b).

This structure can be compared to a stainless steel lead pencil.

Arteriographies performed at the initiation of lengthening, after 6 days of external fixation, and immediately after removal of the intramedullary nails (Figure 4), showed that the medullary artery had remained patent all the time.

No implant migration or skin problems occurred. We found that proper nail contouring ensured stability of bone fragments during lengthening.

Discussion

The Ilizarov lengthening method has revolutionized the biology of bone and bone growth. Preservation of bone environment, periosteum, and particularly, the medullary vascularization, respect of the biological rate of bone growth, use of automatic high-frequency lengthening, preservation of stability and elasticity (provided by the rings): everything works together to provide good to excellent tissue regeneration [3]. The more stable the lengthening site is, the faster it will heal. Though Professor Ilizarov claimed the major role of the bone marrow in new bone formation, a certain number of works disputed the paramount qualitative role of periosteum in distraction osteogenesis [4, 5].

FIN has a proven track record of over 25 years of effective fracture treatment in children based on animal experimentation [1] and above all, on the outstanding experience of the Pediatric Orthopedic Department, Surgical Clinic, Nancy (France). According to data, FIN builds a strong elastic frame that enhances biological effect of redistribution of blood flow to the periosteal structures through cortical canals, thus stimulating formation of periosteal callus. FIN is a semi-rigid elastic nailing system, that allows cyclic micro-scale plastic deformations which is most beneficial for healing. Also, as the two intramedullary nails do not fill in the medullary cavity completely, endosteal callus formation is not inhibited.

We had the idea to combine both elastic systems, Ilizarov and FIN, for limb lengthening [6]. Our animal experiments prove that contoured intramedullary nails do not inhibit endosteal bone formation. On the contrary, despite partial destruction of the bone marrow, the preserved intramedullary circulation stimulates tissue regeneration to such an extent that it becomes necessary to increase the distraction speed to avoid premature consolidation of the regenerate during lengthening.

The biological effect of redistribution of intramedullary blood flow to the periosteal structures stimulates formation of periosteal callus, resulting in extensive periosteal reaction, both along the bone fragments and at the diastasis. FIN provides increased stability at the diastasis by resisting translation motion (essentially) in the plane of the nails. Gradual stretching or sliding of the intramedullary nails through the regenerate during lengthening seems to enhance the regeneration process. However, the mechanism of biological stimulation of endosteal bone formation remains unexplained. Controlled bone marrow irritation by an intramedullary nail is known to produce localized new bone formation [1]. It has been confirmed in animals, when intramedullary nails positioned at the periphery of the regenerate and gradually pulled have shown to accelerate the formation of new bone [7].

Conclusion

FIN can be used together with external fixation for bone lengthening. Combined use of these two methods allows to stimulate both endosteal and periosteal bone formation. FIN improves stability of the bone fragments at the diastasis, and does not inhibit intramedullary circulation. In bone lengthening, FIN is the only internal fixation method that provides the same optimal conditions for bone regeneration as the Ilizarov method. That is why combined Ilizarov/FIN yields such a good outcome. The results of this experimental study have been, in our Kurgan clinic, a determining factor for the use of combined Ilizarov/FIN method in bone

lengthening and correction of bone deformities in patients with limb length discrepancy (LLD) and skeletal pathologies such as hereditary hypophosphatemic rickets.

1.2. TIBIAL LENGTHENING WITH FLEXIBLE INTRAMEDULLARY NAILING WITH HYDROXYAPATITE COATING

As mentioned in the previous chapter, the combined technique of lengthening (external fixator+FIN) boosts bone consolidation. Obviously, it is provided by mechanical peculiarities of osteosynthesis: increase of stability of bone fragments and gradual traction of intramedullary nails along the medullary cavity. This effect manifests only if the intramedullary blood supply is preserved – a fundamental condition of the Ilizarov method.

Figure 5. Radiograph of the *right tibia*. Tibial lengthening by combined Ilizarov/FIN: Ilizarov fixator and intramedullary nails in place, osteoclasis of the tibia(a); X-ray taken after 28 days of lengthening (end of lengthening period) (b); X-ray taken after 7 days (D 40) of fixation period (c). Complete healing achieved after 14 days of fixation period (D 48)(d); external fixator removed (e). Histologic sections (tibia): specimen at D 49 (fixator removed), cortices were present along the regenerate and continuity was re-established.

It is well-known that implants with hydroxyapatite coating, like prosthetic stems, have better adhesion with bone tissue because of biologic reaction of bone formation immediately on the implant without an intermediate fibrous layer. In other words, surfaces of such implants reveal osteoconductive features [8-12].

We held an experiment in dogs, when nails covered with hydroxyapatite were inserted in the medullary canal for tibial lengthening by the combined technique.

The results are presented in this chapter.

Materials and Methods

This study was conducted in 12 dogs of various breeds, aged from 1 to 4 years, with the average weight of 18.2 kg. The mean length of tibia was 181 mm. The applied Ilizarov fixator consisted of two distal rings and two proximal three-quarter rings, connected by threaded rods (Figure 5). The only difference from the series with bioinert intramedullary nails described in the previous chapter was application of lesser number of wires in the Ilizarov fixator. The upper and lower systems contained only three wires each. There was no other difference between the surgical techniques.

Distraction was initiated on the fifth day in all dogs (Figure 5). The mean distraction rate at the beginning was 1 mm/day. Duration of lengthening was 28 days. A 28-day- lengthening period was followed by external fixation period. The external fixator was removed after 15 days of fixation (D 48) in all dogs. All the dogs could bear weight right after removal of the external fixator without any limb protection.

Results were evaluated according to the radiographic appearance of the regenerate. X-ray control was performed weekly throughout the distraction and fixation periods and after frame removal. Additionally, bone regenerates were histologically studied after sacrifice: at D 48 and D 63.

Results

As in the first series, radiological changes indicated intense and extensive bone regeneration, that forced us to increase the distraction speed in some dogs. Newly formed bone was visible on radiographs after D 7 of lengthening. At this stage, the regenerate had an inhomogeneous structure with localized areas of increased bone density. An intensive periosteal reaction (15–54 mm long and 3-10 mm thick) developed by the 2nd-3rd week of distraction period. It caused significant enlargement of bone cross-sectional dimensions (Figure 6).

As control X-rays revealed extensive bone regenerate, the distraction speed had to be increased in 7 dogs. Early healing occurred in four dogs by the 14th-21st day of lengthening. The following lengthening did not result in rupture of the regenerate that had already consolidated (Figure 7). After 15 days of fixation (D 48), the regenerate was completely healed in all the animals. Cortical bone was reconstructed. Continuity of three or four cortices was reestablished along the regenerate. The growth zone had disappeared. A denser periosteal reaction was noted. No fracture or deformity occurred after removal of the external fixator because the regenerates had already consolidated, besides the bones were protected by FIN.

Figure 6. Intensive periosteal reaction: Ilizarov fixator and intramedullary nails in place, osteoclas of the tibia(a); by the end of distraction (D 33) an intensive periosteal reaction developed at a level of the gap and adjacent bone fragments (b); bone consolidation was defined in two weeks of fixation (D 47), bone diameter doubled at a level of lengthening (c); arteriography by the sacrifice revealed a significant osteogenesis in periosteal and endosteal parts of new bone (d). Histologic sections: specimen at D 49 (fixator removed), cortices were present along the regenerate and continuity was re-established. Regenerate consisted of cortical and cancellous bone tissue. The medullary canal was patent. Ossification was present along the intramedullary nails. Periosteal reaction resulted in doubled bone diameter at a level of lengthening (e).

Figure 7. Healing status after 14 days of tibial lengthening using combined Ilizarov/FIN: Ilizarov fixator and two intramedullary nails in place, closed osteoclas of the tibia (a); X-ray taken after 7 days of lengthening (b); X-ray taken after 14 days of lengthening, the gap size did not correspond to the duration of distraction, the bone regenerate is uninterrupted, a continued periosteal reaction at the level of lengthening and bone fragments - consolidation (c); X-ray taken after 28 days of lengthening, no separation of bone fragments (the gap did not increased), wires of the Ilizarov fixator did not gain in curve, the regenerate did not ruptured (d).

At the same time, a histological study showed cortical continuity, fully interconnected cancellous trabeculae and disappearance of the fibrous layer surrounding the new bone

(Figure 5f, 6e). In fact, consolidation happened during the fixation period and lasted 2 weeks. Similar to bioinert intramedullary nails, the extensive tissue regeneration along the intramedullary nail was noted (Figure 5f, 6e).

Arteriographies, performed immediately after removal of the intramedullary nails (Figure 6d), showed exuberant formation of the vascular net in the regenerate and periosteal structures.

Besides, no implant migration, septic complications, secondary displacement of bone fragments or skin problems were observed. An ensured stability of bone fragments during lengthening was noted applying the flexible intramedullary nails with hydroxyapatite coating even if the number of wires in the Ilizarov frame was diminished.

Discussion

Preservation of bone environment, periosteum and, particularly, the medullary vascularization, respect of the biological rate of bone growth, preservation of stability and elasticity (provided by the rings) - all these work together to ensure excellent tissue regeneration [13,14].

Our previous animal experiments prove that contoured titanium intramedullary nails do not inhibit endosteal bone formation. On the contrary, despite partial destruction of the bone marrow, the preserved intramedullary circulation stimulates tissue regeneration.

Mechanical impact of gradual traction of flexible nails in the medullar cavity and increased stability at the diastasis by resisting translation motion (essentially) in the plane of the nails as demonstrated before [14] induce stimulation of the regeneration process.

The added bioactive intramedullary element in this situation appeared to increase a favorable effect of the FIN.

Hydroxyapatite-coated intramedullary nails were chosen because of osteoconductive features of this mineral [15,16]. The fact of solid adhesion between bone and hydroxyapatite implants [8,9,12] was proved. Hydroxyapatite coating provides an early fixation of an implant without a fibrous layer between bone and implant. Soballe et al. [17] demonstrated that the fibrous tissue beneath HA interface contains collagen fibers which are usually perpendicular to the implant surface and can guide bony ongrowth.

Hydroxyapatite-coated intramedullary nails used in the experiment intensified formation of bone distraction regenerate. It ensured consolidation of bone fragments within two weeks after the end of distraction in all cases. The combined technique of distraction osteosynthesis with bioactive implants was performed with a lightened variant of the external osteosynthesis (fewer wires in the Ilizarov fixator).

We believe that use of hydroxyapatite-coated intramedullary nails in combination with external fixation can be indicated in systemic skeletal diseases, associated with disorders of bone tissue formation, impaired metabolism of Ca and P resulted in low bone mineral density.

Thus, the combined technique of lengthening with bioactive intramedullary implants respects all the favorable aspects of mechanical stimulation of bone formation. The use of hydroxyapatite-coated intramedullary nails allows to decrease the number of wires or half-pins of the external fixator with no harm to stability of osteosynthesis. Besides, the bone healing is achieved in the shortest period.

ABSTRACT

Transphyseal sliding nailing of the right intact tibia with thin steel rods was performed in six mongrel dogs at the age of six months. The contralateral segment served as a control. In series II the transphyseal sliding nailing was performed in a fractured tibia also in six dogs. Modifications of residual growth and natural shape-formation of proximal and distal epiphyses of the tibia were observed in the experiment in conditions influenced by the transphyseal rods.

Keywords: growth, tibia, transphyseal sliding nailing.

INTRODUCTION

Skeletal systemic diseases inhibiting strength properties of bone tissue, osteogenesis imperfecta in particular, are very often complicated by pathological fractures, deformities and limb length discrepancy. In 1952, Sofield proposed to perform transphyseal intramedullary reinforcement in order to correct deformities in osteogenesis imperfecta [1]. In this case,

* Corresponding Author's Email: dpopkov@mail.ru.

intramedullary material stay inside for the whole period of growth serving as an internal device during bone fragment union, as well as preventing the development of new deformities. Further development of the technique of transphyseal reinforcement allowed Bayley to create a specific system of transphyseal intramedullary telescopic osteosynthesis [2-6]. In 1987 Métaizeau proposed to use intramedullary sliding transphyseal elastic nailing not only for treatment of common shaft fractures in children, but also to prevent deformities in skeletal systemic diseases accompanied by bone tissue fragility [7].

There are many recent publications which highlight advantages of the telescopic intramedullary transphyseal systems in prevention of fractures and deformities in children affected with osteogenesis imperfecta [8-10]. In 2004, Boutaud and Laville reported fewer complications comparing to use of telescopic rods in their study of intramedullary transphyseal sliding reinforcement in 14 children with osteogenesis imperfecta (36 segments) [11]. Another advantage of elastic nails is a possibility of applying in any medullary canal diameter that is particularly important for children up to the age of 6 years.

As Salter and Harris demonstrated, the growth cartilage is known to be one of the most important anatomic structures in pediatric orthopedic practice [12]. However, there is no clinical or experimental research of the effect of prolonged transphyseal reinforcement with elastic nails on the growth of involved segment.

Thus, the purpose of this study was to evaluate the influence of transphyseal elastic nailing on the residual growth of intact tibia (series I) or on the tibia with transverse shaft fracture (series II).

MATERIALS AND METHODS

Experiments were performed observing 12 mongrel dogs in the period of growth (at the age of six months). The animals were divided in two experimental series (six animals in each). Littermate puppies were used in each separate series. Preoperative X-ray examination confirmed the presence of open tibial proximal and distal growth plates in all the dogs.

The sliding bipolar transphyseal elastic intramedullary nailing of the right intact tibia was performed in the first series (Figure 1) [13]. The left limb served as a control.

Protocol of surgery. Thiopental intravenous anesthesia was used for all the interventions. A proximal titanium nail of 1.8 mm of diameter and 10 cm in length, pre-curved at 40° was inserted from the approach of 2 cm medially to the proper patellar ligament. Preliminarily, an entry hole towards the medullary canal transphyseally by a single maneuver with a surgical awl of 3-mm diameter in the position of the knee flexion. It is through this channel the bent nail was inserted.

A distal nail was inserted retrogradely at the level of medial malleolus also transphyseally. Free ends of the nails were U-bent and impacted into epiphyses in order to prevent their migration inside the bone during residual growth of the segment. Wounds sutured by layers with interrupted stitches. Thus, preventive intramedullary transphyseal osteosynthesis applied for osteogenesis imperfecta was simulated in this series.

In the second series a transverse osteotomy was performed subperiosteally with a vibro-saw at the level of middle third of the tibial shaft from 2-cm antero-internal approach before insertion of intramedullary titanium nails (Figure 2). Fibular shaft integrity was broken by

transcutaneous osteotomy with a chisel. The technique of intramedullary nail insertion was similar to those of the first series, however, the nails were inserted along the entire length of the medullary canal. Thus, in this series intramedullary transphyseal elastic nailing was simulated for pathologic bone fracture in osteogenesis imperfecta.

Postoperative wounds were systematically treated in the postoperative period. The animals were anesthetized using non-steroid anti-inflammatory preparations during the first three days twice a day. Additional immobilization of the operated limb was not performed. The animals moved with full weight-bearing of the operated limb without limitation.

The growth of leg bones in created conditions was studied according to X-ray examination of both legs in AP and lateral views. X-rays were taken on the day of surgery and then once a month for six months (up to the closure of tibial growth plates). Radiography was performed at standard focal distance securing the examined limb with “VEP X Technology Premium VET” radiological device.

Figure 1. Series I: X-rays (D 0, AP view) of the right and left tibiae **(a)**; X-rays (D 0, lateral view) of the right and left tibiae **(b)**; X-rays (M 6, AP view) of the right and left tibiae **(c)**; X-rays (M 6, lateral view) of the right and left tibiae **(d)**.

Figure 2. Series II: X-rays (D 0, AP view) of the right and left tibiae (a); X-rays (D 0, lateral view) of the right and left tibiae (b); X-rays (M 6, AP view) of the right and left tibiae (c); X-rays (M 6, lateral view) of the right and left tibiae (d).

The following parameters were evaluated monthly:

- tibial length was measured by X-rays in the lateral projection of segment axis from tibial condylar articular surface to the ankle gap. The change in tibial length was calculated, as well as the growth length loss comparing with the left tibia (mm and %), the growth for the observation period of the segment final length, and the relative loss of length comparing with the left tibia;
- the amount of crossing of the proximal and distal nails in the medullary canal;
- the diameter of tibial shaft in the middle third (by AP and lateral views of X-rays);
- the mechanical Medial Proximal Tibial Angle (mMPTA) was measured between the mechanical axis of segment and the line connecting two points (tops) of the concave articular surfaces of tibial condyles;
- the mechanical Lateral Distal Tibial Angle (mLDTA) formed by the mechanical axis of segment and the ankle articular line;

- the location of elastic nails at the level of physes relative to their median axes in the sagittal and frontal planes.

Moreover, in series II the time of bone fragment consolidation was evaluated, as well as possible segment deformities resulted from secondary displacement. Statistical analysis included descriptive statistics: mean values (M) and standard deviation (SD). Comparative studies were carried out with Student's t-test and Wilcoxon test for independent and paired samples. Differences in values considered significant at $p < 0.05$. AtteStat 13.1 Program was used to calculate the statistical parameters.

Comparing values within the series were as follows:

- D 0 (day of surgery) vs M 6 (six months after the experiment start) for the right limb,
- D 0 (day of surgery) vs M 6 (six months after the experiment start) for the left limb,
- D 0, the right limb, vs D 0, the left limb,
- M 6, the right limb, vs M 6, the left limb,

The experiments were made in accordance with the requirements of “European Convention for the protection of vertebrate animals used for experimental and other scientific purposes”, and it was approved by Ethics Committee of the Ilizarov Center.

RESULTS

No infectious and neurological complications were observed in any case. Additional surgeries were not required. In all cases the puppies began moving with full weight-bearing of the operated limb in 2-3 days after surgery.

The position of nails relative to physes centers in each series is illustrated in Figure 3. The passage of the nails at the level of distal growth plate was markedly medial due to their insertion through medial malleolus. The nail occupied $0.63 \pm 0.03\%$ of metaphysis area in this zone.

At the level of proximal physis the position of the nails was more central, but also, in most cases, with a tendency to 1-5-mm displacement in the medial direction with respect to bone longitudinal axis. The nail occupied $0.32 \pm 0.03\%$ of the area of proximal metaphysis. The analysis of the tibial residual growth demonstrated in Table 1.

As seen from the data, the growth continued in the dogs of all series. Difference between the initial length and the length of tibiae (of the right and left limbs) by the end of the experiment are statistically significant in all the series. However, a smaller longitudinal increase of the operated tibia is also characteristic for the both series of the experiment, but they are not statistically significant. The value of longitudinal growth loss during the experiment is the least. It amounted to 1-7 mm (from 1 to 5.4%) in series I and from 5 to 17 mm (from 2.8 to 9.5%) in series II, but the growth acceleration of the operated leg was observed in one dog, and the difference in length by the end of the experiment amounted to 5 mm (2.7%).

Figure 3. (Continued).

Figure 3. Location of elastic nails at the level of physes relative to their median axes in the sagittal and frontal planes: proximal tibial physis, series I (a); distal tibial physis, series I (b); proximal tibial physis, series II (c); distal tibial physis, series II (d).

When analyzing directly the value of tibial gain for D 0 - M 6 period in all the series, a 15-18% decrease of this parameter in the operated segment was determined comparing with the control one.

Note: ¹ – significant differences D 0 vs M 6 for this series,
² – significant differences between right and left sides at M 6.

When measuring the extent of overlapping of nails in the medullary canal, it progressively decreased only as long as the tibia grew. In average the decrease of crossing was 13.4 ± 0.9 mm in the first series and 15.6 ± 5.7 mm in the second series by the end of the experiment. There was no significant difference between the series. Migration of the proximal nail inside the bone should be mentioned in two cases of 19 mm and 25 mm in series II. We did not observe the cases of nail inward migration during segment growth in series I.

No reliable differences in mMPTA values of the experimental segment were revealed between themselves and comparing with the preoperative level at different stages of the experiment (Table 2). Slightly marked changes of this value were found in the left (control) segment. However, these changes were statistically doubtful regarding the experimental segment in four cases. Apparently, the transphyseal insertion of elastic nails close to the center of growth plate doesn't significantly influence the mMPTA value

By the end of the experiment mLDTA values of the experimental (right) segment didn't change statistically significantly among themselves and comparing with the preoperative level in all the series. It can be mentioned that this value had a tendency to increase in the first series for the right limb, and that to some reduction – in the second series. As for the control segment, a reliable decrease in the mLDTA angle was revealed by the end of growth comparing with the preoperative values in the both series (Table 3).

Figure 4. Bone consolidation (X-rays, AP and lateral views), series II: D 0 (a); M 2 (b); M 6 (c).

Thus, in our experiment the transphyseal insertion of elastic nails through the medial malleolus resulted in significant slowing down of the physiological decrease of mLDTA angle (physiological valgus deviation of the ankle) in series II.

The change in the values of tibial outer diameter in the middle third occurred upwards in the right and left limbs of all the animals. Significant difference between D 0 and M 6 were observed in series I and II. According to Table 4 data, the increase of shaft diameter was the same for operated and intact limb in series I. As we believe, it points out to an immaterial impact of intramedullary elastic nails on the functional activity of both endosteal lining and periosteum.

The X-ray signs of bone consolidation (disappearance of fracture line, continuity of cortical plates) in series II were observed in all the cases by the end of the second month of the experiment (Figure 4). Secondary displacement of fragments was observed in one animal only being characterized by 7° antecurvation deformity. A significant increase of bone diameter in the animals of this series was observed by the end of the experiment, if we compare both with the initial data and between the control and experimental limbs (Table 4). It is interesting that the most marked periosteal reaction and, consequently, cortical plate thickening occurred on the posterior surface of tibia. It is obvious that osteotomy is a prerequisite for periosteal reaction development under the conditions of the study.

DISCUSSION

Reconstructive orthopaedic interventions in the limbs for the systemic diseases accompanied by bone tissue fragility are intended to prevent deformities or to correct them. A positive effect of such surgeries on patients' functional condition and increase of their motor activity is indisputable [9,10,14-16]. Boutaud and Laville [11] consider that using of intramedullary sliding transphyseal elastic nailing for these purposes is preferable than telescopic rods: no problems with moving elastic nails apart, less total number of complications than with other systems, less incidence of implant migration. Many colleagues performing reconstructive surgeries in children with osteogenesis imperfecta note the common difficulties and/or disadvantages of telescopic systems: need to replace them as far as the child grows, migration of rods or their parts (e.g., threaded ones) when "anchoring" it to the bone (10.5% - 23.7%), telescopic rod deformation (up to 18.8%), the rod fails to elongate (up to 2.1%), the rod's damage (up to 6.9%) [8,17-21]. Thus, the problem of improving telescopic transphyseal systems remains relevant. Moreover, none of clinical studies assesses quantitatively the effect of transphyseally inserted elements on the limb's longitudinal growth, formation of the reinforced segments' epiphyses, or development of angular deformity.

The results of experimental studies on the effect of partial damage of the growth plates varied, but few in number. A negative effect of reaming of the transphyseal canal on the growth function of cartilage was observed in experimental studies of the proximal tibial physis when they simulated the anterior ligament reconstruction of the tibia. Thus, Chudik [22] and Ono [23] performing the anterior cruciate ligament reconstruction in puppies and rabbits found a statistically significant shortening of the operated segment by the end of natural growth. On the other hand, the straight transphyseally inserted wires of 1.3-2 mm in

diameter left in place for less than 12 weeks didn't cause growth dysfunction and consequently shortening in rabbits [24-28]. Epiphyseodesis with this size of wires was observed within the period of 12-24 weeks of transphyseal placement of implants [25,27]. Epiphysiodesis was observed if the wires' diameter exceeded 3.2-3.5 mm [27,28]. Finally, Mäkelä [28] found that injury of over 7% of the growth plate area led to an irreversible epiphysiodesis and segment shortening. On the other hand, the use of biodegradable transphyseal thin rods in rats doesn't lead to epiphysiodesis [29].

In clinical practice, especially in traumatology, the authors' opinion about the effect of transphyseal wire insertion on the growth cartilage function varies. For example, Horn J. et al. describe partial epiphysiodesis and development of angulation during fracture treatment in children [30]. In turn, Yung and Langenhan do not observe the effect of transphyseally inserted Kirschner wires on further growth of the operated limb [31,32].

In our study the injury of physis area was below 6% when the implants remained in place for 25 weeks, and they didn't cause irreversible epiphysiodesis and formation of statistically significant segment shortening. However, the mean length loss was 3.8 mm in series I, and 7.8 mm – in series II. Transphyseal reinforcement with osteotomy (series II) caused a greater shortening of the operated segment. The loss of residual growth of the operated segment was from 14% to 18%. Thus, the growth retardation was found in all the series of our study.

In our study, intramedullary sliding transphyseal nailing influenced the formation of the angle of inclination of the distal tibial articular surface. Eccentric placement of intramedullary nails through the medial malleolus led either to the ankle varus deviation (in series I) with a significant difference between the control limb and experimental one by the end of growth, or, as in series II, to significant inhibition of physiological valgus deviation (mLDTA decrease).

Central transphyseal placement of the nails didn't cause significant angular deviation in any series of the study. Studies of other authors confirm the fact of angular deviation in case of eccentric injury of the growth plate. In 1994 Guzzanti found two cases of knee valgus development because of lateral location of transphyseal canal and tendon insertion into it in their experimental series of the anterior cruciate ligament plasty in 21 rabbits [33]. Seil did not observe angular deviation during residual growth of the segment following a centrally located channel in 18 lambs [34]. The above mentioned studies and our own data confirm the position of Ford [35], that the central injury of the growth plate doesn't cause angular deformities, but can contribute to segment shortening formation, and peripheral epiphyseodesis leads to angular deformity development.

It is important to mention that long presence of the implant is essential for growth function modification in addition to topography and extent of growth plate injury. There are several studies, which demonstrated that acute forming of the transphyseal canal without wire or tendon placement doesn't lead to epiphyseodesis, as well as doesn't cause any disorders of longitudinal bone growth [36,37]. While formation of a narrow epiphyseodesis zone surrounding the permanently present implant is an irreversible cause of growth inhibition in this part of physis [38,39]. At the same time, just a relatively small size of epiphysiodesis (below 7%) allows spontaneous desepiphysiodesis in the process of active growth [28]. We think that repeated epiphysiodeses and spontaneous desepiphysiodeses explain local inhibition of physis function resulting in growth retardation, but not in arrest of growth immediately after surgery.

Both endosteal and periosteal reactions observed during experimental fracture treatment using intramedullary elastic nails are described in some studies [13,40]. The reasons are those referred to the mechanical irritation of medullary canal inner surface on one hand, and those referred to the redistribution of cortical plate blood flow to peripheral structures on the other hand. The endosteal and periosteal reactions in our experimental series were observed as well. However, there was no periosteal reaction in the first series, and the marked endosteal osteogenesis at the level of the contact with nail ends contributed to cortical plate thickening and bone envelope formation around the intramedullary nails. The periosteal reaction was noted in the second series, where bone integrity damage and periosteum detachment were produced. Thus, we believe that it was just a direct mechanical impact that initiated endosteal and periosteal osteogenesis in our study.

It should be mentioned, that we didn't observe disorders of wires moving apart during growth in the medullary canal in the first series, where the segment preventive reinforcement was imitated. These data confirmed the results reported by Boutard and Laville [11], and they demonstrated the advantages of intramedullary sliding elastic nailing over the telescopic rods from this point of view. However, locking of the elastic nail sliding was observed in three cases when bone fracture was simulated (series II). In our opinion, blocking of the nails with endosteal callus at the level of osteotomy may be an obstacle to moving the rods apart.

The intramedullary elastic osteosynthesis for treatment of shaft fractures in children, including pathological ones, is the most common and reliable surgical method used by pediatric orthopedists of many countries [13,41]. It is quite natural that consolidation of bone fragments took place in all the cases and within usual delay in series II of our study.

The encouraging results of using bisphosphonates [22,26,39] and/or implants with bioactive coating [43] in patients with osteogenesis imperfecta encourages us to hope that combination of therapeutic and surgical methods of treatment will contribute to improve the outcomes in terms of both anatomical (longitudinal growth of segments and prevention of deformities) and functional results of treatment.

CONCLUSION

This experimental study has demonstrated that transphyseal elastic osteosynthesis influences on the segment longitudinal growth. The least length loss was observed in the intramedullary sliding transphyseal nailing simulating preventive osteosynthesis.

The eccentric insertion of transphyseal nails causes angular deformity development or slows down the physiological orientation of articular surface. Thus, transphyseal telescopic systems should provide positioning of implant elements in the center of growth plates only.

Endosteal and periosteal reactions to intramedullary implant insertion lead to increase of cortical plate thickness and bone diameter, that may be beneficial in case of combined treatment of osteogenesis imperfecta by pharmacological and surgical methods.

ABSTRACT

Background. The aim of this study is to evaluate the influence of the external fixation associated with intramedullary nailing on the healing index in limb lengthening.

Material and Methods. This study was based on a series of patients with lower and upper limb length discrepancy of different etiologies. We evaluated results of treatment in patients undergoing limb lengthening with the combination of an external circular fixator and intramedullary nailing (154 cases). The Ilizarov frame (133 cases) or Taylor Spatial Frame (21 cases) were used in combination with flexible intramedullary nailing.

Results. In all the groups of patients we observed a significant reduction of the Healing Index – inferior to 30 days/cm. There were 117 complications but only 10 of them influenced on results of treatment. Finally, results are distributed according to categories: I category – 114 cases (74%), IIa – 27 cases (17.5%), IIb – 3 cases (1.9%), IIIa – 9 cases (5.7%), IVa – 1 case (0.9%).

Conclusion. Flexible intramedullary nailing provides multiple advantages to a method of limb lengthening. Flexible Intramedullary Nailing, when correctly applied, respects the bone biological features which are essential for successful limb lengthening. The major effect of application of the combination of external circular fixation with FIN is significant decrease of external osteosynthesis duration.

INTRODUCTION

Gradual lengthening is the most reliable method in treatment of length discrepancy of upper and lower limb segments. Since the 80-s of the 20th century various changes of operative technique have been introduced aiming to improve the anatomic and functional results and to reduce duration of external fixation: lengthening in automatic mode, stimulation by acute compression of the regenerate, bifocal and polysegmental lengthening [1-3].

Actually, there are two possibilities to combine external fixation and intramedullary nailing in bone lengthening. The first one is presented by an association of external fixator and rigid intramedullary nail of 10 mm and more in diameter [4-6]. The second type of combined technique unites the external fixation and *flexible* intramedullary nailing [3, 7-9].

The experimental study described in the first chapters of this book proved that use of flexible intramedullary nails provides a favourable effect on formation of distraction regenerate. Encouraged by the experimental series, a clinical study was launched, in 2001 in an adolescent affected with a congenital shortening of a lower limb. Currently our technique takes a reliable and important place in the therapeutic arsenal of pediatric orthopedics.

The aim of this study is to demonstrate how the flexible intramedullary nailing influences the outcome in lengthening of upper and lower limbs.

MATERIALS AND METHODS

We have studied results of 154 limb lengthenings in patients of the age between 3 to 22 years old (the mean age at the beginning of lengthening was 11.2 ± 0.17). Lengthening was performed in 79 cases in girls and in 75– in boys.

Lengthening was performed with the Ilizarov fixator (121 cases) or Taylor Space Frame (TSF®) (33) during the period 2001 - 2008 in two clinics: in the Ilizarov Scientific Center for Restorative Traumatology and Orthopaedics (Kurgan, Russia) and in the Children's Hospital of Nancy University Hospital Center (Nancy, France). Surgery was performed by the authors of this study during the years 2001 - 2010.

An inclusion criterion was upper or lower limb lengthening performed with the combined technique if results could be assessed in 12 months minimum after frame removal.

The distribution of cases according to the aetiology, type of distraction osteosynthesis, mean age at the beginning of lengthening is presented in Tables 1 and 2.

It is worth of mentioning that in the group of acquired discrepancy the limb length inequality developed as a result of post-traumatic epiphysiolysis or the physis damaged by the hematogenous osteomyelitis or osteoarthritis. Sequela of hematogenous osteomyelitis caused the lower limb length discrepancy in 15 cases, premature posttraumatic closure of the growth plate in 13 cases. Among the upper limb length discrepancy, sequela of osteomyelitis was observed in 12 children, consequences of the physis lesion – in 7 cases. For the group of

paralytic shortening the reason of length inequality of lower limbs (2 pts) was poliomyelitis, of upper limbs (4 pts) – the obstetrical trauma of a brachial plexus.

Table 1. Variants of distraction osteosynthesis in lower limb lengthening

Segment	Type of distraction osteosynthesis	Congenital		Acquired		Paralytic		Ollier disease		Neurofibromatosis, fibrous dysplasia	
		Nb	Mean age	Nb	Mean age	Nb	Age	Nb	Mean age	Nb	Age
Femur	Monofocal+FIN	19	12.5± 0.98	9	13.7± 0.9	1	16	4	12.5±1.9	1	8
	Bifocal+FIN	7	11.2± 1.7	5	12.2± 0.6						
Tibia	Monofocal+FIN	22	11.3± 1.17	6	9± 1.5	1	15	1	11		
	Bifocal+FIN	7	11.7± 2.1	2	15± 1.0						
Femur+Tibia	Polysegmental+FIN	13	13.2± 0.8	6	11.7± 1.4			2	16.5±3.2	1	14
Total		68		28		2		7		2	

Table 2. Variants of distraction osteosynthesis in upper limb lengthening

Segment	Type of distraction osteosynthesis	Congenital		Acquired		Paralytic		Exostotic disease	
		Nb	Mean age	Nb	Mean age	Nb	Mean age	Nb	Mean age
Humerus	Monofocal+FIN	3	10± 6.0	3	9.7± 2.19	2	11.5± 3.5		
	Bifocal+FIN			13	13± 0.59	1	16		
Forearm	Monofocal+FIN	18	9.9± 1.04	3	13± 0.58	1	16	2	6.5±0.5
Humerus+Forearm	Polysegmental+FIN	1	7						
Total		22		19		4		2	

Monosegmental monofocal osteosynthesis in combination with FIN of the femur or tibia was done in 64 cases. Monosegmental bifocal distraction osteosynthesis of the femur or tibia was applied in 21 cases. Polysegmental distraction osteosynthesis of the lower limb was applied in 22 patients.

Monosegmental osteosynthesis in combination with FIN of the humerus was done in 8 cases. Bifocal distraction osteosynthesis of the humerus was applied in 14 cases. Monosegmental osteosynthesis of the forearm was used in 24 cases. Polysegmental distraction osteosynthesis of the upper limb was applied in only 1 patient.

Surgical Technique

The first stage of the surgery, a classical procedure, consists of application of the external fixator followed by the osteotomy via a percutaneous incision that preserves the periosteum and intramedullary vascularization [10, 11].

The second stage is application of FIN: through two incisions of 1 to 2 cm in the metaphyseal area two entry holes are made in the bone very oblique to the osteotomy by means of the trocar of 3-4 mm in diameter at a distance of 1.5 to 3 cm from the growth plate. For the femoral lengthening FIN is retrograde, starting from the distal metaphysis, if the lengthening is performed in the lower third of the segment. For the tibia (Figure 1), it is antegrade through the proximal metaphyseal approach. As for the humerus, the approach is distal at the level of the lateral supracondylar area with a retrograde FIN.

Figure 1. Surgical technique. Application of two Ilizarov rings, tibial osteoclasis and intramedullary nails. The two curved nails are inserted into the intramedullary canal in anterograde direction. The maximum curves are above the osteoclasis site. Their distal ends are bent (a). During the lengthening the nails slide with the proximal fragment (b). Note: significant periosteal reaction both at the level of diastasis and at the adjacent bone fragments, regenerate is dense and significant (c), after frame removal (d).

Two steel or titanium nails of the diameter from 1.5 to 2.5 mm are pre-curved with the ray of curvature about 40 to 60° and their tips of 1.5 to 3 mm are curved at 30 to 40°. The tip of every nail is blunt. The nails must be bent in a way that allows assembling two intersecting arches. The two nails opposed to each other are situated in the same plane creating the same geometric system - elastic and resistant, which is the same for a diaphyseal fracture. An important difference is that the nails have a smaller diameter in comparison to those used for fracture management.

We used intramedullary nails of 20 to 25% of medullary canal diameter in order to avoid its blocking by external fixator wires or half-pins during distraction period.

The two nails must be carefully introduced one by one up to the osteotomy site, then pushed through it until they finally reach the opposite metaphysis. Rotation of the curved blunt tip allows to avoid the half-pins and wires of external fixator, while inserting a nail along medullary canal, straight or deformed. The maximum curve should be placed near the osteotomy site in the diaphyseal part that enables to cross the nails above the osteotomy. In these conditions the lengthening slowly moves the apex of the nail curvature and it is situated at the level of the growing zone of the regenerate by the end of lengthening period (Figure 1).

If a bone segment is straight, the initial curvature of both nails must be identical. In a case of bone deformity, the arch of one nail can be more curved for maintaining a permanent tension that helps the angular correction during the lengthening. Another solution is to reorient both nails, opposing their concavity to the bone deformity.

External tips of intramedullary nails are bent at over 90° to avoid their migration into the medullary canal during the distraction period, and then they are cut as usually 5 to 10 mm from the bone. The skin is sutured.

The bifocal lengthening can also be associated with FIN. In this case a bipolar variant of nailing is more appropriate. Thus, for example, for the tibia, one antegrade nail is inserted through the proximal metaphysis, while the distal retrograde nail is inserted through the distal metaphysis (Figure 2). During the lengthening period the implants slide along one another in the same way as in a technique for the osteogenesis imperfecta. After the frame removal both regenerates remain reinforced at least by one intramedullary nail curved and oriented in a way opposing the natural tendency of the secondary deformity.

In a case of forearm lengthening we use a tension assembling with a nail in the radial bone, which concavity is oriented to the ulna, and vice versa in the ulna bone. In all the cases the nailing is retrograde in the radius, inserted through an incision of 1.5-2 cm above the distal physis, avoiding superficial nerves and veins, and it is antegrade in the ulna, inserted through a posterior-lateral approach of the olecranon (Figures 3, 4).

A distinction of the external fixator associated with FIN is an ability to attach additional wires or a half-pin after insertion of intramedullary nails. It concerns the frontal wire at a level of the distal femur or proximal tibia or also certain wires of the intermediate ring in the bifocal lengthening. Thus, all the external wires which can interfere the passage of the intramedullary nails in the medullary canal are inserted after FIN.

Lengthening begins on the 4-6th day after the surgery. Limb function is preserved by an early articular mobilization and weight bearing according to usual indications of the lengthening method.

Figure 2. (Continued).

Figure 2. Bifocal lengthening of tibia: X-rays of the tibia before surgery (a), on the 30th day of distraction period (b), by the end of fixation period (6 weeks), cortical continuity, disappearance of growth zone of regenerate (c), after frame removal, amount of lengthening – 7 cm, HI – 15.6 d/cm (d), FIN removal performed in 5 months (e), patient before, during and after treatment (f).

Figure 3. Example of forearm lengthening: nailing is retrograde in the radius and antegrade in the ulna.

Combined deformities are progressively corrected in all the patients during the lengthening period. With the Ilizarov technique, hinges are positioned according to the center of rotation of angulations CORA [12]. With the TSF®, the correction is progressively obtained simultaneously with lengthening following the instructions of the computerized program [13, 14].

Implants are removed in two steps. The external fixator can be removed at the beginning of bone consolidation according to radiographs and clinical test. A precise date is difficult to determine: when the “growth zone” has disappeared and the radiographic continuity of at

least 3 of 4 cortices is observed. Total weight bearing is allowed by the end of six weeks after Ilizarov fixator removal but a semicircular plaster cast is permanently applied for the period of 2 to 4 weeks. The removal of nails is possible in 2 to 8 months after frame removal.

Figure 4. (Continued).

(f)

(g)

Figure 4. Forearm lengthening and cubital club hand deformity correction in a boy 6 y.o. with multiple exostoses: X-rays before surgery (a), in the beginning of the distraction period, the lengthening of ulna will be performed with intramedullary nailing, the deformity of the distal radius will be without lengthening (b), after correction, the first days of fixation period (c), after frame removal, gain of lengthening – 4 cm, HI – 22.3 d/cm (d), in a year after frame removal et 6 months after FIN removal (e), patient before and during treatment (f), functional outcome in a year after frame removal (g).

A general classification of results of bone lengthening [15] is applied to evaluate the outcomes.

This classification (Table 3) is based on the respecting of a triple contract (gain of lengthening, projected treatment duration, and functional outcome):

- grade I: the triple contract is fulfilled, procedures are undertaken under local anesthesia and/or medical treatments are necessary but no intervention under general anesthesia is undertaken;
- grade II: the triple contract is also fulfilled but unscheduled intervention(s) under general anesthesia are necessary. These procedures can take place before the end of the lengthening program (grade II-a) or after the end of this program (grade II-b) without changing the date of external fixator removal;
- grade III: pursuing treatment is necessary beyond the planned period to obtain bone union, but at term, no alteration of function is observed. The HI is therefore lengthened with the external fixator removal or total weight bearing delayed beyond the scheduled time. In grade III-a, the length gain is greater than or equal to 75% of the initial objective, whereas a gain less than 75% is classified as grade III-b. It is possible in grade III-b that bone union takes place within the normal time delay with a HI less than 45 days/cm, but since the scheduled correction has not been obtained, the patient, who desires so, could request a new surgery; this can result in a new therapeutic period;
- grade IV: despite the different treatments, sequelae exist at the final evaluation when the gain is 75% or higher (grade IV-a) or less than 75% (grade IV-b). Whether or not the initial objective of treatment is met, loss of function means worsening of the earlier functional state.

Table 3. Description of the four-grade classification

Grade	I	II-a	II-b	III-a	III-b	IV-a	IV-b
Surgery with general anesthesia	No	Yes before ^a	Yes after ^a	Possible	Possible	Possible	Possible
Planned length gain obtained	Yes	Yes	Yes	Yes	No	Yes	No
Planned duration respected	Yes	Yes	Yes	No	No	Yes/no	Yes/no
Function respected	Yes	Yes	Yes	Yes	Yes	No	No

^a Removal of external fixator.

Statistical analysis was performed using the software AtteStat®.

RESULTS

The average amount of lengthening was 5.1 ± 0.2 cm, the relative average amount of lengthening made 20.3% of the initial length of a segment. It is important to assess the relative lengthening for each segment separately, including polysegmental lengthening.

Radiographic evaluation revealed the following features of formation of the distraction regenerate. In our series the regenerate was always dense and significant. In the majority of cases starting from the third week of lengthening the regenerate was well structured and filled the entire gap between the bone fragments. Its “growth zone” was 2 to 5 mm and abundantly filled with bone trabeculae, while the periosteal reaction increased. The diameter of the regenerate exceeded the diameter of bone fragments by 2 to 6 mm because of the periosteal reaction at the level of diastases and adjacent bone fragments as well (Figure 1).

Tables 4, 5 and 6 present the gain of lengthening and healing index in groups of patients differed by type of external osteosynthesis and etiology of limb length discrepancy (Figures 5 and 6). It is important to note that in all the groups the HI was inferior to 30 days/cm. We can take it as reference data to compare our results with the HI published by other colleagues in “Discussion”. Only in one case the HI was 33.2 days/cm in 16 y.o. patient presented paralytic lower limb length discrepancy: monofocal tibial lengthening was performed in sequelae of poliomyelitis.

Figure 5. (Continued).

Figure 5. Femoral monofocal lengthening in a boy presenting posttraumatic lower limb length discrepancy: X-rays before surgery (a), on the 7th day of distraction period (b), on the 30th day of distraction period (c), at the end of distraction period (58 days) (d), after frame removal, gain of lengthening – 6 cm, HI – 20.5 d/cm (e), in 7 months after frame removal, FIN removal performed (f).

Figure 6. (Continued).

Figure 6. Polysegmental lower limb lengthening in a girl with congenital lower limb length discrepancy: X-rays before surgery (a), on 21st day of distraction period (b), fixation period (c), after frame removal, total gain of lengthening – 6 cm, HI – 15.8 d/cm (d), FIN removal performed in 4 months (e), patient before, during and after lengthening of the left leg (f).

Complications were noted in 103 patients (66.9% of cases). The Table 7 presents all the complications observed in our series as well as the treatment applied.

It should be noted that complications were of I, II-a or II-b categories in 107 cases, meaning the final results of treatment were not compromised and the planned therapeutic objectives were achieved without any sequelae.

We want to emphasize, there were no pathologic fractures after frame removal in patients presenting bone diseases with fragility (Ollier disease, fibrous dysplasia) (Figure 7).

Figure 7. Use of combined technique of limb lengthening in the patient with fibrous dysplasia: bifocal femoral lengthening and deformity correction by hybrid external fixator (Ilizarov+TSF) associated with FIN (a), after frame removal FIN remained in place (b).

Table 7. List of complications according to severity grade

Complications	Treatment	Number
<i>Grade I: gain, HI, and function fulfilled - intervention without GA</i>		77
Local infection with pins or wires	Local care $\pm$ antibiotic therapy	55
Paresthesia, temporary paralysis	Surveillance, removal of wire in contact, no GA	9
Threat of early bone union	Acceleration of elongation speed	6
Delay in appearance of bone regenerate	Slowing down of elongation speed	2
Migration of FIN	Percutaneous nail pushing, no GA	5
<i>Grade II-a: gain, HI, and function fulfilled - intervention with GA before end of lengthening program</i>		27
Local infection with pins or wires	Pin or wire removal and replacement	7
Migration of FIN nails	Cutting, nail pushing or early removal of FIN nails	7
Problems with ExFix: deviation of assemble, cutaneous contact, instability	Revision of ExFix with GA	4
Breakage of ExFix material, screws	Material removal with GA	5
Early union of regenerate	New osteotomy	3
Infection of osteotomy hematoma	Surgical cleansing and antibiotic therapy	1
<i>Grade II-b: gain, HI, and function fulfilled - intervention with GA after the end of the lengthening program</i>		3
Migration of FIN nails	Early removal of FIN nails	3
<i>Grade III-a: gain and function fulfilled, HI > 45 days/cm</i>		9
Joint stiffness	Mobilization with GA, tendon elongation	6
Fracture and deformity after EF removal	Immobilization cast, epiphysiodesis or osteosynthesis	3
<i>Grade III-b: function fulfilled, gain not obtained, HI > 45days/cm</i>		0
<i>Grade IV-a: function not fulfilled (sequelae), gain obtained</i>		1
Posterior knee subluxation	Secondary progressive correction with EF	1
<i>Grade IV-b: function not fulfilled (sequelae), gain not obtained</i>		0

In the majority of cases (143 pts) the intramedullary nails were removed in 3-8 months after removal of the external fixator.

Prior to analysis of treatment results according to the principles of Lascombes classification [15], it is important to mention that 14 patients developed two complications. In such situation a more severe complication has been taken into consideration in assessment of the final result (Figure 8).

Thus, the results were categorized: I – 114 cases (74%), II-a – 27 cases (17.5%), IIb – 3 cases (1.9%), III-a – 9 cases (5.7%), IV-a – 1 case (0.9%).

Figure 8. (Continued).

Figure 8. Patient T., 7 y.o., neurofibromatosis, type I: X-rays of lower limbs and foot of the patient before treatment (a), X-rays of the lengthened femur, fixation period (b), local infection near two wires in the distal ring caused their removal (c), fracture at the level of regenerate in 3 days after frame removal (d), bone consolidation obtained with valgus deformity (e), internal distal hemiepiphysiodesis by 8-plat (f), correction of the valgus deformity achieved in 14 months (g), X-rays after plate and FIN removal (h).

DISCUSSION

Improvement of bone lengthening procedure by means of external fixation remains topical. The duration of fixator wearing is often long because of the healing index, that makes from 35 days/cm to 65 days/cm according to several publications [7, 16-19]. It may cause multiple complications. Eralp et al. [205] mention the index of 1.65 month/cm in lengthening of the tibia by the Ilizarov fixator, and Sluga et al. [14] in application of the TSF – 48.4 days/cm. The index of consolidation usually obtained by conventional Ilizarov method is 24 to 30 days/cm in femoral or tibial lengthening and 30 to 40 days/cm in the forearm [3].

According to data of Donnan et al. [21] the HI makes 46.4 days/cm in femoral lengthening and 37.3 days/cm in tibial one when applying monolateral fixators of the Orthofix type. After McAndrew et al. [22] – 40.8 days/cm. Besides, the authors mix all the etiologies including achondroplasia, congenital, post-traumatic discrepancy and so on, that we consider unjustified. In some publications analyzing the treatment period one can find the authors' opinion on influence of various factors on the period of consolidation. Thus, Matsubara et al. [5] precise that the HI decreases to 42.5 days/cm in combination of gradual lengthening by the Ilizarov fixator or TSF with the gradual correction of associated deformities in comparison to the acute correction in the beginning of lengthening, when the HI makes 58.6 days/cm. El-Mowafi et al. [23] describe a favourable effect of low-frequency

stimulation of bone regeneration with the ultrasound: the HI reduces from 48 to 30 days/cm of lengthening. Finally Kim et al. [4] state that the nailing of a lengthened tibia with a nail of a diameter of 10 mm allowed to decrease the HI to 40.53 days/cm. In simultaneous ipsilateral femoral and tibial lengthening with the Ilizarov method, Curran observed in 4 patients the average femoral healing index of 28 days/cm and the average tibial healing index of 29 days/cm [16].

Besides, some acceleration of treatment can be achieved by different ways [2, 11, 24]. In addition to known methods of lengthening, we propose to unite two methods for the limb lengthening: the gradual distraction with the Ilizarov fixator or TSF and FIN [3, 25]. This combination enables to add certain advantages of the elastic intramedullary nailing to all the improvements of the distraction osteosynthesis.

Our previous comparative studies have shown that the combined technique (circular ExFix+FIN) allows the mean HI reduction of 7 days/cm or to decrease the distraction-consolidation time by 20% in limb lengthening [3, 25].

Other authors also reported this effect of HI reduction using a ring fixator with FIN [7, 8]. Furthermore, accelerated bone consolidation was observed in a short series of femur lengthening, where the monolateral Orthofix fixator was applied with FIN [9].

In contrast to combined methods of distraction osteosynthesis using intramedullary rigid nail [4-6], application of elastic nail reveals an advantage to combine lengthening with progressive deformity (axial and/or rotational) correction. This approach makes additional prealignment procedure unnecessary [3, 25, 26]. The second undisputable advantage of our method is a possibility to perform it in children without any risk to damage the physis. Clearly, an insertion of a rigid nail cannot avoid partial destruction, at least, of one growth zone.

Besides, the benefit of a reduced HI is a low rate of complications. We observed a significant decrease, even absence of those complications which are caused by long distraction-consolidation delay: pin/wire site infection, joint stiffness, hemorrhagic complications at pin site, as well as complications caused by low rate of bone regeneration: delayed consolidation (HI superior to 45 days/cm), deformity or fracture after frame removal [17, 27-29]. FIN left in situ allowed to minimize and even eradicate such specific problems as pathologic fractures at the level of fibrous or cartilaginous zone in our series of patients presenting diseases associated with bony fragility (fibrous dysplasia, Ollier disease) [30, 31].

So, the demonstrated and proved advantages of the combined method for limb lengthening (ExFix+FIN) are reduction of HI, low rate of septic, articular and bony complications, prevention of pathologic fractures. Finally, we observed the good and excellent results in 93.5% of cases in this series.

The results are scored as good or excellent only if the planned length gain was achieved, planned duration of treatment was respected, there was no any complication impairing functional outcome, e.g. without sequelae.

It is worth of mentioning that only perfect performing of FIN associated with the Ilizarov fixator allows to respect all the obligatory conditions of the distraction osteosynthesis (Ilizarov method), namely, preservation of the bone surrounding, periosteum and especially intramedullary vascularization, respecting of biological rates of lengthening, preservation of the function by an early articular mobilization and weight bearing, respecting certain biomechanical rules. So, all the conditions are united in a way that enables association of indisputable advantages of FIN with the Ilizarov method of lengthening by means of the

Ilizarov frame itself or TSF. Nevertheless, the result depends first of all on the personal experience of the surgeon in both the limb lengthening technique and the flexible intramedullary nailing [3, 25].

CONCLUSION

The flexible intramedullary nailing, a low invasive and elegant method, allows to add multiple advantages to the method of limb lengthening with the external fixator. This combination seems to us well proved and logic. FIN, when correctly applied, respects the bone biological features which are essential for successful limb lengthening. The major effect of application of the combination of external circular fixation with FIN is a significant decrease of duration of the external osteosynthesis.

ABSTRACT

Introduction. Prognosis of limb length discrepancy in children affected by congenital abnormality remains a subject of concern. Therapeutic strategy must take length prediction into account in order to adapt equalization techniques and the timing of treatment. Initial prognosis, however, may need revising after completion of one or several surgical interventions on the pathologic limb.

The aim of this study was to determine different types of growth response that a bone segment can present after progressive lengthening in case of congenital limb length discrepancy.

Materials and methods. Treatment results were analyzed in 150 patients with congenital lower limb length discrepancy, who underwent surgery at age from 2 to 15 years old. Bone segment growth rates were measured before lengthening, during the first year after frame removal and, finally, over long-term follow-up, calculating the ratios of radiological bone length to the number of months between two measurements. Mean follow-up was 5.1 ± 1.3 years.

Results. Changes in short- and long-term growth rate distinguished five patterns of bone behavior after lengthening, ranging from growth acceleration to total inhibition.

* Corresponding Author's Email: dpopkov@mail.ru.

Discussion and Conclusion. These five residual growth patterns depended on certain factors causing acceleration or, on the contrary, slowing down of growth: age at the lengthening surgery, percentage of lengthening and minimal period between two lengthenings. These criteria help to optimize conditions for resumed growth after progressive segmental lengthening, avoiding conditions liable to induce slowing down or inhibition, and providing a planning aid in multi-step lengthening programs.

Keywords: congenital lower limb length discrepancy, bone lengthening, residual growth

INTRODUCTION

One of the major issues of the long-term follow up after limb lengthening remains the change of longitudinal growth function of the operated segment.

Residual growth after progressive lengthening has been the focus of several studies [1-9], but the evolution of congenital lower-limb length discrepancy in children undergoing progressive lengthening remains unforeseeable and the factors relevant to bone segment activity in these cases remain undetermined. Both slowing and boosted growth patterns have been reported, independently of the lengthening technique employed (Judet, Wagner, Callotasis or Cauchoix) [2-6], other authors finding no change in growth rates [7-9].

The present retrospective study sought to identify factors affecting residual growth after progressive lengthening: age at lengthening, percentage of lengthening, and single- or multistep strategy.

MATERIALS AND METHODS

We studied outcomes in 150 patients with congenital unilateral limb length discrepancy (girls/boys=79/71), to whom Ilizarov lower limb lengthening was performed at age from 2 to 15 years old (the average 8.3 ± 2.9 years old). The series was homogeneous for etiology and surgical procedure. In total the patients underwent 207 stages of surgical segment lengthening. In 42 cases the segment was lengthened twice and in 15 – thrice.

Femoral lengthening gain ranged from 1.5 to 7 cm reaching the average of 4.2 ± 1.43 cm or $17.3\% \pm 12.18\%$ of the initial segment length. The index of fixation ranged from 2 to 47.3 days/cm (the mean 15.2 ± 12.03 days/cm), the healing index – from 11.8 d/cm to 66 d/cm (the average 29.9 ± 17.56 d/cm)

Tibial lengthening gain ranged from 2 to 7 cm reaching the average of 4.8 ± 2.38 cm or $19.3\% \pm 11.04\%$ of the initial segment length. The index of fixation ranged from 3.3 to 44.3 d/cm (the mean 15.7 ± 10.41 d/cm), the healing index – from 10 to 73.3 d/cm (the average 28.6 ± 13.0 d/cm).

In this series of patients the natural growth of a shortened limb was assessed before surgical treatment, in 1-3, 6-8, 9-12 months after the treatment and during 3-7 years of the long-term follow up.

Hechard-Carlio charts [10] were used for monitoring femoral and tibial longitudinal growth. Preoperatively, predicted limb-length discrepancy and final segment length were

assessed with multiplier method [11] taking into account that, without treatment, the natural growth of a malformed segment is linear, with a constant rate, so that change in percentage discrepancy will likewise be linear [12].

To investigate possible growth-rate change after lengthening, whether stimulation, transitory slowing of growth during the first year or definitive cessation of growth, the following index was calculated at end of growth phase:

$$\text{RGG (\%)} = (\text{PFSSD} - (\text{LG} \pm \text{FRSD})) \times 100\% / \text{FLSL}$$

where: RGG = residual growth gain; PFSSD = predicted final spontaneous segmental discrepancy (mm); LG = length gain achieved by external fixation (mm); FRSD = final residual segmental discrepancy (mm: healthy segment length minus lengthened segment length); and FLSL = final lengthened segment length (mm).

This index represents the change in spontaneous growth after progressive lengthening with respect to the final length of the lengthened segment; it may be positive (growth stimulation), neutral (no change) or negative (slowing of spontaneous growth).

RESULTS

Observing the longitudinal growth we distinguished the following types of change of the growth rate of the operated segment in short and long-term follow up.

Type I – increased growth rate by the end of lengthening progressively decreasing by the 9-12th month after the end of treatment, but the growth rate remains higher than initial during the long-term follow up (Figures 1, 5 and 6).

Type II - increased growth rate returning to the initial one by the 9-12th month after frame removal. In the long-term follow up the growth rate is close to preoperative (Figure 2).

Type III – growth rate increase is observed during the first postoperative year but in the long-term follow up the growth rate is slower than initial (Figure 3).

Type IV – immediate inhibition or absence of longitudinal growth of the segment is observed till the 6-8th month after the end of surgical lengthening followed by returning to the initial growth rate (Figure 4).

Type V – progressive decrease of the growth rate after the treatment down to full stop for several months followed by stabilization of the growth rate at values inferior to initial (Figure 4).

Tables 1 and 2 demonstrate change of the mean growth rate of lengthened femur and tibia in various groups of patients.

Comparing various groups to each other according to the relative amount of lengthening and healing index, no statistically significant difference was found. Choice of a method for femoral or tibial lengthening also had no significant influence on change of the following growth type. Distribution of cases between the groups of patients is of a proportional character. Reconstructive surgery on foot bones is of a great importance whether performed simultaneously with tibial lengthening or during the long-term follow up. In such cases the

tibial growth rate is slower than initial. This correlation was noticed even in the primary lengthening: two patients with growth rate of type II and III and four patients with type V.

Figure 1. Diagram of segment growth (dotted line corresponds to bone lengthening, A – growth of short tibia, B – growth of normal tibia, C – growth of short femur, D – growth of normal femur): type I of residual growth of lengthened segments.

Figure 2. Diagram of segment growth (dotted line corresponds to bone lengthening, A – growth of short tibia, B – growth of normal tibia, C – growth of short femur, D – growth of normal femur): type II of residual growth after the first lengthening, type V after iterative lengthening.

Figure 3. Diagram of segment growth (dotted line corresponds to bone lengthening, A – growth of normal tibia, B – growth of short tibia): type III of the residual growth.

Figure 4. Diagram of segment growth (dotted line corresponds to bone lengthening, A – growth of short tibia, B - growth of normal tibia): type IV of the residual growth after the first lengthening, Type V – after iterative lengthening.

Figure 5. Case of femoral lengthening: photo of patient K., 11 y.o., X-rays of short femur, before treatment, (a); during lengthening (b); after frame removal, HI – 21.9 d/cm (c); photo of the patient at the age of 15 years and X-rays of lengthened femur (d).

Table 1. The mean values of growth rate in lengthened femur at different periods of observation

Groups of patients according to the growth type	Femoral growth rate at different periods of observation; mm/month				
	Before surgery	2-3 months	6-8 months	9-12 months	Long-term follow up
I	1.38±0.47	3.05±1.84	2.8±0.86	2.3±0.94	1.6±0.60
II	1.35±0.20	1.53±0.41	1.36±1.19	1.3±0.21	1.37±0.10
III	1.4±0.33	1.59±0.29	1.3±0.37	1.15±0.62	0.9±0.20
IV	1.26±0.30	0.22±0.37	0.55±0.48	2.03±1.02	1.8±0.64
V	1.27±0.74	0.43±0.62	0.33±0.58	0.42±0.40	0.24±0.65

Table 2. The mean values of growth rate in lengthened tibia at different periods of observation

Groups of patients according to the growth type	Tibial growth rate at different periods of observation; mm/month				
	Before surgery	2-3 months	6-8 months	9-12 months	Long-term follow up
I	1.13±0.29	2.6±0.96	1.51±0.68	1.8±0.53	1.48±0.27
II	1.24±0.31	2.7±2.03	-	1.25±0.25	1.25±0.35
III	1.1±0.46	3.7±2.43	2.1±0.56	0.76±0.37	0.73±0.28
IV	1.16±0.30	0.21±0.32	1.20±1.56	1.3±1.29	1.7±0.48
V	1.18±0.50	0.34±0.49	0.4±0.42	0.43±0.43	0.6±0.40

Comparison of group I and group V according to the data presented in Table 3 allows the statement that second and third stage of femoral lengthening necessitates inhibition of a natural segment growth. On the other hand, it is the primary surgical lengthening of the segment that stimulates the following growth.

Table 3. Distribution of femoral growth types according to the stage of lengthening; number of observations

Growth type	Primary lengthening	Second lengthening	Third lengthening
I	49	1	0
II	18	0	0
III	12	3	0
IV	5	0	0
V	6	20	7

Table 4. Distribution of tibial growth types according to the stage of lengthening; number of observations

Growth type	Primary lengthening	Second lengthening	Third lengthening
I	59	0	0
II	21	2	2
III	5	0	0
IV	11	4	0
V	8	24	11

In tibial lengthening we also observed inhibition of natural growth after consecutive lengthening (Table 4). After primary lengthening the decrease of longitudinal growth rate was noticed in presence of severe malformation of a proximal femur or if the lengthening was performed at age of 13-15 years old, i.e., prior to the end of natural growth. Reconstructive osteotomies on foot bones in 4 cases were associated with inhibition of longitudinal tibial growth in the long-term follow up even after the first lengthening.

(a)

(b)

Figure 7. Relations between RGG (in boys) and age of lengthening, in cm (a) and % (b).

Figures 7 and 8 shows correlation between the age at the beginning of treatment and residual growth gain in the first stage of lower limb lengthening. Since the bone age of 8.5-9 years in girls and 12 years in boys the stimulation of longitudinal growth of the lengthened segment is not observed.

(a)

(b)

Figure 8. Relations between RGG (in girls) and age of lengthening, in cm (a) and % (b).

Besides, the age at the beginning of the second stage of lengthening and delay between stages are important for the following growth of segment. Figure 9 demonstrates influence of the age at the beginning of the second stage of lengthening and the time period between the stages on the following longitudinal growth of segment.

According to the above mentioned data it is obvious that in order to prevent the inhibition of the following growth, the second stage of lengthening should be performed before prepubertal growth acceleration and the most favorable delay between the lengthening stages of the same segment is about four years.

(a)

(b)

Figure 9. Relations between RGG and age of iterative lengthening (a) or RGG and delay between two lengthenings of the same segment (b).

If the same segment was lengthened twice, all patients manifested inhibition of longitudinal growth with negative value of residual growth gain. Absolute length loss was 5.0 ± 1.27 cm, relative $-11.9 \pm 2.84\%$. Thereat, total amount of lengthening in femur was 15 ± 2.25 cm and in tibia -13.8 ± 1.92 cm. Thus, triple lengthening of a segment during the period of natural growth is considered inexpedient.

DISCUSSION

In congenital lower-limb length discrepancy, lengthening procedures often need to be performed before the end of spontaneous growth, due to the functional and psychological impact of the discrepancy on child and family. Prognosis of the growth of an operated limb is an important component of lengthening strategy.

The present series exclusively included congenital pathology, making it homogeneous. As congenital discrepancies show a percentage length difference that remains stable over growth in absence of treatment, we accepted the hypothesis that any observed change in growth pattern would be identical across all congenital etiologies, independently of segment location.

Growth stimulation following a first Ilizarov lengthening procedure was systematic when bone age was less than 12 years in boys or 9 years in girls.

This mechanism may be explained by stimulation due to increased vascularization during lengthening, or by a mechanical cause [5]. Some reports stressed the importance of having a correct biomechanical axis and of functional loading to minimize disturbance of conjunctive cartilage growth over periods exceeding 2 years [13,14]. Experimental studies showed that cell number per column in the growth area depends on the forces acting on the cartilage, increasing with increased loading. The greater the number of cells, the more active the cartilage [15]. Antonov demonstrated the growth-stimulating effect of functional forces under dynamic loading [13]. Absence of functional weight-bearing can slow down the longitudinal growth. It explains inhibition of tibial growth while reconstructive surgeries on foot simultaneously with tibial lengthening. External fixation allows all deformities to be progressively corrected, avoiding impairment of joint range of motion during lengthening and ensuring a perfect biomechanical axis in three dimensions [16-18].

Penneçot et al. [2] reported a significant impact on the growth plate after progressive bone lengthening by Judet distractor. The harmful effects of hyperpressure on the conjunctive cartilage, impaired vascularization and the resultant shaft ischemia may account for subsequent slowing of growth. However, the 1-2 mm initial joint-line distraction reported by Oostenbroek et al. was probably insufficient to prevent contact between the joint surfaces and avoid shaft compression [19]. Joint bridging avoids inducing subluxation and hyperpressure threatening the conjunctive cartilage. In the present series, there was no significant difference in residual growth rate associated with bridging of the knee, and no conclusion can thus be drawn as to whether bridging, performed basically to avoid joint impairment, also protects the tibial shaft.

The reduction in growth observed, however, was not necessarily related to the hyperpressure effects described by the above authors. Obtaining and maintaining a normal axis during the lengthening procedure seems to us to be a necessary but not sufficient condition for growth to be conserved.

Percentage lengthenings emerged as one of the main factors impacting residual growth. An experimental study, however, reported that a lengthening of 30% did not affect longitudinal tibial growth [20]; these conclusions were drawn from morphological results at only 5 weeks' follow up. Clinical data, in contrast, demonstrate the negative impact of such a length gain. Viehweger et al. [6], in series of 34 children, reported a clear impact on residual growth following lengthening exceeding 30% using a unilateral external fixator. One of our

studies [21] demonstrates that single-step lengthening of more than 30% of initial segment length is to be avoided in congenital lower-limb length discrepancy, as it may impair resumption of growth.

Osseous age at time of lengthening is a factor to be taken into account in treatment planning in congenital lower-limb abnormality. Pouliquen et al. [3] reported that lengthening performed before the age of 11 years induced growth disorder; this series, however, included only six children with congenital discrepancy. The present results, on the contrary, showed greater growth stimulation gain in children aged less than 8 years at time of procedure. These findings are in agreement with those of Suva et al. [5], who reported accelerated growth of a mean 2.5% in all children treated at less than 6 years of age.

In our study has shown that lengthening performed after the start of the pubertal growth boost (here taken as after 12 years' bone age in boys and 10 in girls, due to the impossibility of having a reliable physiological estimate of pubertal maturity) led to a negative RGG and all the more so in the early phases of puberty.

The exact mechanism of slowed growth can only be guessed at. During the intense pubertal spontaneous growth phase, the soft tissue of the lengthened segment cannot adapt to the change in length, which may result in hyper pressure on the growth plate. Suva et al. [5] suggest a phenomenon of growth capital exhaustion to account for slowing.

It also emerged that iterative lengthening of the affected segment induced negative RGG when conducted at close intervals (of less than 3 years). These findings may guide planning length equalization when the discrepancy prognosis requires iterative lengthening: iterative lengthening of a segment should be undertaken before the beginning of the pubertal growth boost but more than 3 years after the first procedure. The alternative is to perform the second lengthening around the end of spontaneous growth. This program can thus be applied to manage severe femoral or tibial hypoplasia.

CONCLUSION

Our results prove that the primary lengthening of lower limb segments in congenital length discrepancy, which is performed before the prepubertal growth acceleration, can be a factor stimulating the following natural growth.

The second stage of lengthening of the segment leads to inhibition of growth of the operated segment. The least inhibition is noted when the delay between two stages of lengthening of the same segment is about 4 years. Another unfavorable factor is performance of reconstructive surgeries on foot both simultaneously with tibial lengthening and during the long-term follow up.

Triple lengthening of the segment during the natural growth should not be performed at all.

All these data should be considered while planning the strategy of surgical treatment of children with congenital lower limb length discrepancy.

Chapter 5

BIOACTIVE IMPLANTS IN RECONSTRUCTIVE ORTHOPEDICS

Arnold Popkov*, PhD, MD

Scientific and Clinical Laboratory for Deformity Correction
and Limb Lengthening. Federal Russian State-Financed Ilizarov Scientific
Center for Restorative Traumatology and Orthopaedics, Kurgan, Russia

ABSTRACT

Detailed description of methods of external circular osteosynthesis in association with flexible intramedullary nails with bioactive coating in deformity correction are presented in Chapter V. It is concerned with surgical treatment of orthopedic disorders in such diseases as osteogenesis imperfecta. In this part of the monograph we describe various currently existing bioactive coatings of implants, used in orthopedic practice and new developing trends of this field.

Keywords: flexible intramedullary bioactive coating, implants, intramedullary nailing

1. TYPES OF BIOACTIVE COATINGS AND IMPLANTS

Reconstruction of organs or skeletal parts affected by trauma or disease still remains quite challenging for the state-of-the-art traumatology and orthopedics. There are two different approaches to resolving of this problem nowadays: 1) simple substitution of an affected bone by an implant of mechanical integration or 2) creating the conditions for bone regeneration with spontaneous total recovery or by means of an implant of biological integration.

Analysis of the contemporary reference data proves that both trends are related to bioceramics. Perspectives of use of bioceramics are determined first of all by the possibility to change mechanical and biologic features of implants and their approaching to the bone

* Corresponding Author's Email: apopkov.46@mail.ru.

tissue. We recall that the bone has complicated structure and diverse tissue constitution. Mechanical characteristics of the compact bone are determined by specific 3D position of its structural components – bone lamellae of 3-10 mkm thick [1,2]. Bone matrix (collagen) makes up about 20-25% of total weight of bone, non-organic component (Ca phosphates) - 60-65%, content of water reaches 9-10%. Besides, there are small amounts of other organic compounds (proteins, other than collagen, polysaccharoses, lipids).

Organic bone matrix and non-organic components create a specific composition material. Contemporary bioengineering is not yet able to reproduce artificially the morphology of bone tissue in detail, thus, to achieve the same combination of biologic and mechanical features as of the bone. Nevertheless, biomaterials acting as implants should meet the following requirements:

- 1) Chemical features - absence of unwelcome chemical reactions with tissues and intertissue liquid, absence of corrosion;
- 2) Mechanical features of biomaterial should be close to those of the bone – strength (flexibility) and resistance to fatigue deformities and fractures;
- 3) Bioactivity of the material – absence of reaction of the immune system, osteoconductivity (ability to develop microvessels on the material surface and then osteogenic cells with formation of the bone tissue, also inside transverse pores of the optimal dimension) and osteoinductivity (ability of the material for adhesion and differentiation of mesenchymal stem cells including osteoblasts and stimulation of their osteogenic function). Osteogenity and osteoinductivity provide biointegration of implants.

Bioinert metals and alloys with ceramic coating on the bases of Ca phosphates (especially hydroxyapatite) are supposed to be the best for creating orthopedic implants for the locomotor system going through strong mechanical stresses. These materials provide biologic compatibility and significant biologic activity in bone formation around the metal.

Practical application and improvement of those implants are developed in the following directions:

- 1) Design of joint replacement implants: their metal load-bearing element is covered with hydroxyapatite aiming to create excessive bony sleeve providing secure contact of the metal with the bone tissue along the maximum surface, which exclude insufficient fixation of joint elements on the bone for long term.
- 2) Design of intramedullary implants for substitution of vast bone tissue defects resulted from trauma or radical excision in orthopedic or oncologic surgeries.
- 3) The reconstructive combined surgery definitely involves the second direction. As the contemporary ceramics is fragile, it covers metal layer (usually in a form of titanium, stainless steel nails of 1.5-3 mm diameter). Such covering is capable to induce reparative osteogenesis around the implant promoting bone defect substitution. Thus, a sleeve, formed along the entire implant, provides optimal conditions for healing bone fractures or pseudoarthroses, for formation of distraction regenerate in limb lengthening.

A weak point of those implants is necessity of a secondary surgery for their removal in 3-6 months after fracture consolidation, healing of bone fragments. This disadvantage is supposed to be conventional as removal of the implant is not obligatory.

Definitely, the solution of this problem suggests itself as to create an intramedullary implant made of solid composite material, which is progressively resorbed while the defect is getting filled with a newly formed bone. The first ones of those implants are composites of “hydroxyapatite – polymer” type, they manifest mechanical features similar to the bone and highly bioactive.

Development of those materials started by the end of 70s of the previous century, aiming to create artificial bone substitutes. In 1980s W. Bonfield et al. developed a composite consisted of hydroxyapatite particles and high density polyethylene [3]. Hydroxyapatite particles of 4 μm diameter were dispersed and uniformly distributed in the polymer *matrix*. Polyethylene is a typical material known for its consistency and rigidity, but manifesting no bioactivity. On the contrary, HA possesses bioactivity, but not consistency. Uniting these two materials results in products possessing consistency and bioactivity at the same time.

It was determined that if HA has a higher Young's modulus of elasticity than polyethylene, thus, this modulus of the composite “hydroxyapatite-polyethylene” rises with increase of volume ratio of HA-filler and can reach the modulus of cortical bone [3]. Nevertheless, composites lose consistency and become fragile when HA-content exceeds 45%. Y.Wang et al. also studied influence of dimension of HA-particles on mechanical properties of this composite material [4,5]. It turned out that composites with a lesser size of particles possess a higher modulus of torsion and extension and a higher tensile modulus of elasticity. The surgeon can easily pre-shape the composite during surgery, which is also an advantage of the material.

As polyethylene is not bioactive, so, when implanted, it is encapsulated with fibrous tissue and isolated from surrounding tissues. To provide bioactive properties, the content of HA particles should exceed 20% [3]. Exposure of HA-particles on the composite surface is necessary for providing bioactivity, as there should be direct contact between bioactive particles and surrounding tissues to induce the effect of osteoconductivity.

Thus, the “hydroxyapatite-polyethylene” composites with HA-content rate of 20-40% possess the consistency and Young's modulus similar to the ones of natural bone and the bioactivity. A combination of hydroxyapatite and polyethylene proposes a new material for bone substitution close to the bone by its mechanical properties. It is already used in orbital floor fractures to build up volume, and as a material for middle ear implants.

Other composites were composed of polyethylene and Bioglass® [5]. Bioglass® is bioactive glass revealing high level of bioactivity with both hard and soft tissues. In those composites the Young's modulus and microhardness grow with increase of Bioglass® content, though breaking tensile strength and strain to failure decrease. The composites build a layer of bone-like apatite on their surface [6,7].

Juhasz et al. reported about glass-ceramic A-W-polyethylene composites [8]. Glass-ceramics is distinguished for its high mechanical strength and bioactivity [7], that is why it is supposed to be an effective filler in bioactive composites. Increasing the A-W glass-ceramics content in those composites causes an increase in Young's modulus, yield strength and bending strength, and a decreased strain to failure [9]. The composites demonstrate high ability to produce apatite in simulated interstitial fluid, also increasing with increase of A-W glass-ceramics volume.

Composites “hydroxyapatite – poly-L-lactide” (u-HA-PLLA) contain poly-L-lactide (PLLA). This biodegradable polymer is used in fabrication of medical devices applied in clinical practice in orthopedic, cranio-maxillofacial surgery. Those devices have some weak points, like lesser strength than of the natural cortical bone, slow rate of degradation and no osteoconductivity. In order to improve bioactivity and mechanical strength of the polymer, its combination with bioactive ceramic fillers were developed. Some authors reported about composites with Ca phosphate fibers or particles of baked hydroxyapatite which are dispersed in biodegradable organic polymers. Though, those materials could not be resorbed completely. Other attempts were to add resorbable polymer to bioceramics, but those materials had low mechanical strength [10].

Shikinami et al. [11] reported development of composites “HA – PLLA”, when hydroxyapatite requires no thermal processing. Unbaked powder of hydroxyapatite (u-HA) was prepared by reaction between calcium hydrogen phosphate anhydride (CaHPO_4) and calcium carbonate. It resulted in carbonate containing hydroxyapatite. HA congeries were broken and sifted to receive particles of a diameter rang 0.3-20 μm , in average - 3 μm . U-HA particles were dispersed in polymer PLLA-matrix to fabricate composites “u-HA - PLLA”. The given composite possessed high mechanical strength. U-HA particles were uniformly distributed in matrix and exposed on the surface providing bioactivity. Bending strength of the material increases with increase of u-HA content. It reaches about 270 MPa with a 30 vol% u-HA filler content. This value is higher than in PLLA samples without filler and much higher than in human compound bone. Bending strength of the composite is also a little higher than in PLLA samples without u-HA and close to the value of human compound bone. Impact index of the composite with a 30 vol% u-HA filler content is much higher than the one of PLLA samples without u-HA or of human compound bone [12].

Biological properties of composites “u-HA – PLLA” were studied *in vitro* and *in vivo*. *In vitro* tests showed formation of bone-like apatite on the surface within 3 days after soaking in simulated body fluid. It suggests that the composites are bioactive. *In vivo* tests of implantation in bones of animals revealed that devices made of composites demonstrate more affinity to the bone than those made of PLLA: fibrous tissue formed on surfaces of the latter, while using of composites resulted in formation of bone-like apatite and direct contact with the bone. Histological study showed that new bone formation occurred in 2 weeks after implantation. Such bioactivity of those composites induces an early position stability of implant in bone. Gradual degradation of the implanted composite in the bone defect was observed to result in replacement of the composite by bone tissue. When the u-HA - PLLA composite rods were implanted in a subcutaneous layer, their bending strength preserved 85% of the initial value in 8 weeks and 80% in 25 weeks, while the molecular weight of the rods reduced to 20% of the initial value over the same period [13,14].

Healing of a fractured human bone normally requires over 8-12 weeks, though the healing period is determined by various parameters, like fracture location, stability of bone fragments, patient's age. Stability of osteosynthesis is believed to be a very important factor during healing, so, in order to maintain stable fixation during this period, the mechanical strength of an intramedullary or on-bone device should be preserved. Despite the fact that the u-HA – PLLA composite demonstrated a faster degradation in bone defects than PLLA alone, fabricated with the same technique, but devices made of this composite preserve mechanical firmness during the entire period of fracture healing.

Shukinami et al. reported total degradation of rods for bone fixation made of “u-HA – PLLA” composite in approximately 4.5-5 years after being implanted: passages created in the distal femoral condylar for implanting were almost totally filled in with new bone [11]. There was no inflammatory response to biodegradation or bone defect substitution.

Thus, analysis of literature revealed that research in ceramics-polymer composites creation reached the level of commercially affordable proposals and the concept of combining of non-organic and organic components seems to be logic in developing material for bone reconstruction.

Choice of this or that material depends on medical-biologic characteristics of the bone defect as well as on a concrete clinical case. So, solution of this problem is possible upon availability of the whole range of biomaterials. Choosing the most appropriate material for the concrete case allows to the surgeon to shift from reconstructive-substitutive principle of treatment to a higher level of bioengineering.

Currently, tissue engineering is one of the youngest branches of medicine, it is based on the principles of molecular biology and genetic engineering. A multidisciplinary approach used in this sphere is aimed to create new biocomposite materials for recovery of lost functions of certain tissues or organs [15,16].

Basic principles of this approach are development and implantation of bases made of biodegradable material into the damaged organ or tissue, which are used in association with donor cells and/or bioactive materials. In the latest years, new technologies allow to extract bone morphogenic proteins (BMPs/BMP-2 and BMP-7) and use them in clinical practice.

Recombinant human osteogenic Protein-1 (rhOP-1), inducing *in vivo* formation of new bone tissue and possessing specific activity similar to natural osteogenic protein, stimulates proliferation and differentiation of osteoblasts *in vitro*. It is able to induce formation of bone tissue by stimulation of mesenchymal stem cells and their following differentiation into precursor osteogenic cells. Administration of rhOP-1 into the bone defect gap and fracture site provides total recovery of the bone in 30 months.

One of the major tasks of tissue engineering in treatment of bone pathologies is creation of synthetic composites which are able in combination with bioactive molecules to induce osteogenesis as well as chondrogenesis in reconstruction of joint surfaces (the latter has not found a practical application yet). Besides, such materials should possess certain properties of the bone [17,18,19]:

- to scaffold the defect volume,
- to possess osteoinductive capacity,
- to be biocompatible, i.e., to be able to biodegrade and not to provoke inflammatory response of the recipient.

All those properties together allow to such materials along with a supportive function to provide biointegration – ingrowth of cells and vessels into the implant structure, and stimulate bone tissue formation around the implant.

Tissue engineering implies using of cells in complex with biologic or artificial matrixes which conduct cells in the process of reparation. Implant fabrication should be rather cheap and clinical application with osteoinductive capacities should guarantee consolidation of injured bone in the shortest period possible: consolidation of a simple fracture of long bones

should not exceed 3-4 weeks, as for formation of the distraction regeneration in bone lengthening, the time of regenerate mineralization allowing to remove the external fixator should tend to zero (the process of mineralization must coincide with the process of formation of organic matrix).

Currently, the intramedullary implant in a shape of a titanium HA-coated wire meets all the requirements: production is rather cheap, practical application does not require use of expensive donor cells and artificial bioactive materials (OP-1, rhOP-1). Intramedullary space, bone marrow and endostium contain the entire set of morphogenetic proteins, ferments and growth factors, a great number of mesenchymal stem cells and endosteal osteogenic cells, needed for differentiation to osteoblasts and proliferation of the bone substance around the intramedullary nails.

Concept of Bone Tissue Formation on the Intramedullary Implant Surface

Nowadays, understanding of basics of the reparative regeneration in “skeletal tissues” provides development of tissue engineering in orthopedics and traumatology, first of all because of unsatisfactory time and results of fracture healing. When the contemporary science states that fractures require at least 12 weeks for healing and real time of patient’s rehabilitation takes 10-12 months, when the healing index in limb lengthening 45 days/cm [20-22], the situation naturally needs development of medical technologies stimulating the reparative process.

The Ilizarov scientific school always held to the concept of sufficiency of proper body reserve for healing of limb fractures and maintenance of optimal conditions for reparative bone regeneration that means:

- thorough, preferably close reduction of bone fragments,
- stable fixation of bone fragments,
- low invasive surgery,
- adequate blood supply of the fracture or limb lengthening site,
- optimal rate and rhythm of distraction,
- functional weight bearing of the limb during treatment.

Economic expediency is the basis of elaboration of the method of transosseous osteosynthesis aimed to osteogenetic induction. In 2001 D. Popkov suggested to lengthen long tubular bones by means of flexible intramedullary nailing. First, Ilizarov Scientific Center (Kurgan, Russia) started to apply the technique, then Pediatric Orthopedic Center (Nancy, France). As a result, reinforcement of reparative osteogenesis around flexible nails and reduction of healing time were noted [23-25].

In our opinion, the intramedullary osteosynthesis by nails with bioactive coating performs two functions – provides additional stability of bone fragments as well as all osteoconductive and osteoinductive conditions for reparative bone tissue regeneration characteristic to HA-based materials.

From the economic point of view, the production technology of nails with bioactive calcium phosphate coating is an inexpensive process [26,27], and intramedullary positioning

of the implant excludes necessity of additional cultivation of high-cost growth and cell factors.

Titanium nails are coated with biologic or synthetic hydroxyapatite produced by low temperature method [28]. According to the results of electronic microscopy, the present HA sample is a powder mixture with pallets inclusions of nanoscale structure of 10-100 nm diameter. According to X-ray phase analysis, the powder is a heterogeneous hydroxyapatite mixture of hexagonal and monoclinal structure with the internal surface area over 70 m²/g. The coating technology of titanium nails of 1.8mm diameter is based on electrochemical deposition. In average the coating thickness is 85±3.0 µm, surface roughness – 5.5±0.01 µm. According to the results of AFM of fine resolution, the coating pattern consists of nodules of approximately 100 nm diameter, of approximately 35 nm height, and flaky fragments. They form spherulites of about 5 µm in diameter and up to 300 nm in height. In the middle of spherulites and in between them there are transverse pores of the diameter below 1-2 µm reaching metal base surface. Electronographic image of titanium coating of nails viewed micropore diameter of 2 to 5 µm (Figure 1).

The flexible intramedullary nailing with bioactive HA-coating allows to influence on the bone marrow activity stimulating endosteal bone formation by the very presence of the nail. Its internal stress induces the function of mesenchymal tissue of the bone marrow (mechanoinduction of osteogenesis). This method of osteoinduction is characterized by low traumatism, it preserves the nutrient artery, and excludes possibility of delayed consolidation.

Formation of bone tissue on the ceramic implant surface requires adhesion of certain molecules. The bone structure is hierarchically organized in various ranges of length – from macro- to nanoscale, thus, the implant structure also should be hierarchically organized in three levels: macro- , micro- and nano-. Besides, nano surface pattern should be approximately 100 nm in order to conform with cell receptors and the pores are needed of micro- and macro dimensions. The recommended dimension of micro pores is at least 300 µm which provides nutrition and cell distribution on the implant surface as well as formation of capillaries in it.

Figure 1. Surface of the intramedullary titanium nail (scanning electron microscope) x1500 (a); x5000 (b).

Studies of ectopic osteogenesis on the ceramic implant surface showed that bone tissue formation is obligatory preceded by cell migration and angiogenesis which are observed only

if there is a sufficient amount of micropores, otherwise, ectopic formation of the new bone can slow down or fail. It is well known that not porous materials don't manifest osteoinductive properties.

Figure 2. Surface of an intramedullary nail at 26th day of experimental study (scanning electron microscope, x3000). Through holes in the protein film can be seen the hydroxyapatite coating.

We determined that immediately after implantation of biomaterial, proteins of blood and extracellular matrix (Figure 2) – fibronectin, osteocalcin, bone sialoproteins, immunoglobulin, albumin, etc. – are absorbed on the biomaterial surface.

We believe that osteoinduction is related both to the design of the implant surface pattern and to a biological phenomenon of inflammatory response developing after implanting of biomaterials [29,30]. Caplan A.I. and Boyan B.D. [31] hypothesized that initial inflammatory response to implanting of biomaterials stimulated factors attracting mesenchymal stem cells. One of them can be prostaglandin E2 (PGE2) produced by macrophages accumulated around biomaterials during the inflammatory phase [32,33]. The microrough surface, unique for osteoinductive materials, reported to stimulate production of PGE2 by macrophages [32] and PGE2 possesses hemotoxic features towards human mesenchymal stem cells and stimulates their osteogenic differentiation.

As a result of flexible intramedullary nailing, a certain bony sleeve forms around the nail because of inducing of the local osteogenesis. Figure 3 demonstrates CT images of dog's tibiae – intact and undergone intramedullary osteosynthesis. Shades of bony sleeve around the canal of intramedullary nail are clearly seen inside the marrow cavity. Thickness of a mineralized wall of this “sleeve” ranges from 1 to 3 mm. The bone tissue ingrows into pores of the implant surface and rapidly fills in all the space of marrow cavity firmly uniting nails with endosteum (Figure 3). Cancellous bone forms as a natural bone scaffold in fracture.

Osteoconductive and osteoinductive properties of flexible implants, that we developed, provide directional growth of new bone tissue in the fracture site, as well as in the limb lengthening gap, in correction of systemic diseases (osteogenesis imperfecta, Ollier disease, fibrous osteodysplasia, rickets-like diseases), in substitution of bone cysts; they also favor finishing of bone histogenesis in postnatal period in place of cartilaginous or connective matrix [34].

Figure 3. The bone tissue formation around intramedullary nail: intact tibia, computed tomography (a); lengthened tibia, after nail removal (b); bone trabeculae formation on the HA-coated surface of intramedullary nail (c); cancellous bone tissue filled in the space around the intramedullary nail (d).

2. USE OF INTRAMEDULLARY BIOACTIVE NAILING IN OSTEOGENESIS IMPERFECTA

Deformity Correction and Intramedullary Telescopic Constructions

Basic surgical methods of treatment of deformities in children affected with osteogenesis imperfecta are corrective osteotomies and a basic mode of osteosynthesis is intramedullary [35-41,45,51,52,54]. Considering the fact that in OI all the limbs are involved, it is recommended to use reference data for treatment planning [41,42,49]. When levels and amount of deformity correction are determined, a number of required osteotomies and amount of correction at each level is calculated [44,47]. It is important to correct all the deformity components of the entire limb within one surgical session, as the deformities are often counter-directed and compensate the above and below segment axis [40,44,54]. Preventive

osteosynthesis of long bones as well as osteosynthesis in fractures are performed using intramedullary telescopic transphyseal constructions [37,46,51,53,54].

Figure 4. Application example of intramedullary transphyseal flexible osteosynthesis in a two-year-old female patient: X-rays of right and left lower limbs before treatment (a), photo of the patient (b); before surgery the child could not walk and stand. AP X-rays of limbs, lateral X-rays of femurs after insertion of flexible nails (c), the child began to stand with weight bearing on limbs in 3 months (d) and to walk independently in 5 months (e).

Among the basic intramedullary telescopic constructions there are

1. Flexible intramedullary nailing (FIN) [38,44];
2. Telescopic Bailey-Dubow nail [35-37];
3. Telescopic Fassier-Duval nail [41,48,54].

But the use of those telescopic systems is not devoid of complications [43,55].

We have developed and use transphyseal osteosynthesis with HA-coated bioactive intramedullary nails. Specific features of the coating providing osteoconductive and osteoinductive characteristics [48,50] are described in the previous chapter.

The procedure (Figure 4) starts with insertion of elastic, pre-curved along the entire length, mostly titanium nails of 1.5 to 4 mm diameter. The nails are smoothly contoured that produces two opposing curves. They are inserted towards each other from the opposite epiphyses or apophyses transphyseally. An important aspect of the passage through the physis

is use of a trocar or a surgical awl and performance of this maneuver at a single-attempt in order to avoid excessive trauma of the growth zone.

The nails can be advanced through the medullary canal to the opposite epiphysis without prior reaming. If the canal is very narrow or absent at all, the reaming of these parts of the bone is performed through the same approaches as osteotomies. Very often realignment osteotomies require one or several incisions to advance the wire under visual control.

FIN is the most effective method of osteosynthesis in deformity correction of the upper limbs. Indications for the surgical treatment are more frequent in forearm deformities, impairing use of the upper extremity in daily routine [40,53]. It is the small diameter of forearm bones that implies application of intramedullary nails of the 1.5-3 mm diameter for osteosynthesis of bone fragments after corrective osteotomies (Figure 5).

Figure 5. Example of forearm deformity correction: X-rays of the forearm before surgery (a), after deformity correction and intramedullary flexible nailing (b).

Strong and Weak Points of This Method of Osteosynthesis

HA-coated FIN definitely preserves all advantages of the intramedullary elastic osteosynthesis with titanium or steel nails [38,44]. This method of osteosynthesis can be used almost in all bone dimensions.

Besides, if the marrow cavity is obliterated, preliminary reaming of fragments, even moderate, allows to insert elastic nails of a small diameter. This method of osteosynthesis permits to stabilize bone fragments in multilevel osteotomies. Elasticity of osteosynthesis provides distribution of the weight bearing along the entire medullary canal which is favorable for bone consolidation and does not impair strength properties of cortical plates. Intramedullary telescopic constructions prevent secondary fractures, even if they occur, bone fragments remain stable without significant displacement. Also, telescopic character of FIN scaffolds the bone while it is growing; stabilizing features of intramedullary nails are preserved if they overlap each other by 30% of their proper length and more. Besides, the HA-coating dramatically decreases nail migration in the long-term follow-up.

Results of assessment of how hydroxyapatite coating influences on preservation of mineral density in the operated segment are presented below.

A disadvantage of the technique is exclusion and then restriction within several weeks of the total weight bearing on the operated limb. Such a motion behavior causes decrease of the bone mineral density. In the long-term follow-up it is necessary to change nails while the bone growing in length and in diameter.

Combined Technique

In the Ilizarov Center we use combined osteosynthesis (external fixation and flexible intramedullary nailing) for severe multilevel deformities [48].

The technique is supposed for correction of deformities of lower limbs in children affected with osteogenesis imperfecta. It is based on a combined application of the transosseous osteosynthesis with the Ilizarov device and intramedullary osteosynthesis with bioactive HA-coated nails which provide prophylactics of deformity relapse. Application of the Ilizarov fixator allows to start weight-bearing on the operated limb from first post-operative days and to prevent secondary torsion deformities.

Technical Performance in Limb Deformities

Taking into consideration that lower limb deformities involve, as a rule, both the femur and tibia, polysegmental osteosynthesis of the limb is recommended, i.e., both segments should be operated simultaneously. Surgical procedure can be monofocal or bifocal in each segment depending on extensivity and amount of the deformity (Figure 6).

The surgery begins with insertion of intramedullary titanium nails with bioactive coating. In order to perform it, an oblique tunnel is made through a cortical layer into medullary cavity via a cutaneous incision of 8-10 mm long on lateral and medial surfaces of the metaphysis by means of a 4-5 mm diameter awl. An HA-coated nail is inserted through the tunnel. The nail diameter (2-3.5 mm) depends on the diameter of the intramedullary canal. In this pathology the marrow canal is often irregular or even absent at some locations, thus, insertion of nails is challenging for a surgeon and requires specific instruments.

Figure 6. Bone segment scheme of application of intramedullary nails in the combines technique: the segment before deformity correction (a), 1 and 2 - canals for intramedullary nail insertion; the segment after deformity correction and intramedullary nail insertion (b), 3 and 4 - inserted intramedullary nails into the medullary cavity.

A special device (Figure 7) can be used to guide and ensure a necessary direction for insertion of the nail according to the shape of medullary canal and bone deformity. It is also important, if the medullary cavity is absent (eburnation) or of a small diameter and needed to be drilled with a wire.

A flexible curved nail is inserted in the medullary cavity via guide. If the medullary cavity is patent, the nail is usually easy to introduce manually up to the opposite metaphysis. When the guide is taken out, a free nail end is cut and bent. A U-shaped bend should prevent nail migration into the medullary cavity during distraction, and, at the same time, make it possible to grip the tip with a special instrument for removal in several months after limb lengthening.

If there are small thin bone trabeculae crossing the medullary cavity and the surgeon does not intend to traumatize the canal by drilling, a special pusher (Figure 8) is used.

A severe bone deformity associated with osteoporosis usually renders impossible to insert the nail by the full length of the medullary canal at one time (as the nail easily perforates the bone cortex), so at the level of deformity apex (if angulation is up to 20°) a corrective hinge osteotomy should be performed. Then, having performed an acute axial alignment of the limb, the nail is introduced in the proximal bone fragment. If the deformity exceeds 20° , the intramedullary nailing is technically feasible only after closing wedge osteotomy at the deformity apex and its acute correction.

When the nails are inserted, then the soft tissues are sutured and transosseous osteosynthesis of a shorten limb segment is performed with Ilizarov fixator assembled according to the goals of the surgeon. A clinical case illustrating this surgical technique is presented below.

A Clinical Case

A female patient K., 6 years old. Diagnosis: osteogenesis imperfecta, combined deformities of lower limbs and contractures of hip and knee joints (Figure 9a,b). In anamnesis: multiple close fractures of lower limb bones treated conservatively.

(a)

(b)

Figure 9. (Continued).

Figure 9. Female patient K., 6 years old, osteogenesis imperfecta: X-rays of lower limbs before treatment (a), photo before treatment (b), photo during deformity correction with Ilizarov device (c), X-rays of lower limbs after treatment (d), photo and functional abilities of lower limbs in one year after treatment (e).

The patient underwent a consecutive deformity correction of lower limbs and flexible intramedullary nailing with HA-coating (Figure 9c,d). Rehabilitation took an average recovery time, control of long-term follow-up revealed complete functional recovery of the limbs and no deformity relapse in 18 months after treatment (Figure 9e).

Bone Mineral Density Study Results

In twenty patients of the age range from 4 to 27, who underwent polysegmental combined osteosynthesis with the Ilizarov frame and HA-coated flexible intramedullary nailing, bone mineral density was assessed (dual-photon bone densitometer “GE Lunar Corp”, USA) at the metaphyseal level of operated segments. Also measurements were taken at L2, L3, L4 levels. Assessments were done in 30 and 60 days after surgery, in 6 and 12 months after removal of the Ilizarov device.

The aim of study was to evaluate dynamics of bone mineral density of operated segments and lumbar vertebrae in conditions of an early activation of patients in postoperative period and using bioactive implants. It is worth of mentioning, that during the study period the patients were not administrated bisphosphonates.

Before surgery the bone mineral density value was 53.6% ($p<0.001$) of the value of healthy people in a proximal femoral metaphysis, where nail insertion was planned (Table 1). By the 30th postoperative day the bone mineral density increased by 9.6% ($p<0.05$) of the initial one. By the time of Ilizarov frame removal (60 days) it reached 19.5% ($p<0.001$). In 6 and 12 months the bone mineral density value always remained higher then initial.

Such a bone mineral density dynamics is noted in a distal femoral metaphysis (Table 2), a proximal tibial metaphysis (Table 3).

Table 1. Mineral density in a proximal femoral metaphysis ($M\pm SD$)

Period	Mineral density, g/cm ²	
	Metaphysis	Cortices
Normal value	1.570 $\pm$ 0.108	1.680 $\pm$ 0.101
Before surgery	0.841 $\pm$ 0.059	1.277 $\pm$ 0.102
After surgery		
D 30	0.922 $\pm$ 0.054*	1.433 $\pm$ 0.086*
D 60	1.005 $\pm$ 0.080*	1.519 $\pm$ 0.106*
After frame removal		
6 months	1.051 $\pm$ 0.079*	1.289 $\pm$ 0.104*
12 months	1.062 $\pm$ 0.069*	1.340 $\pm$ 0.094*

Note: * significant difference ($p<0.05$, Student's t-test) in comparison to the initial value.

Total amount of mineral substance in L2, L3, L4 vertebrae (Table 4) in patients before treatment was in average by 20% less than in healthy people. By the 30th postoperative day there was a tendency to bone mineral density increase, in average by 3.8% ($p<0.05$). In 60 days after surgery the increase reached 12.1% and became statistically significant in comparison to the preoperative bone mineral density level ($p<0.05$). Ilizarov frame removal did not influence on mineral substance content in the spine. During the following year of follow-up its amount did not change.

Table 2. Mineral density in a distal femoral metaphysis ($M\pm SD$)

Period	Mineral density, g/cm ²	
	Metaphysis	Cortices
Normal value	1.410 $\pm$ 0.098	1.546 $\pm$ 0.106
Before surgery	0.635 $\pm$ 0.051	0.983 $\pm$ 0.079
After surgery		
D 30	0.710 $\pm$ 0.046*	1.079 $\pm$ 0.086*
D 60	0.786 $\pm$ 0.044*	1.167 $\pm$ 0.070*
After frame removal		
6 months	0.785 $\pm$ 0.058*	1.168 $\pm$ 0.064*
12 months	0.797 $\pm$ 0.048*	1.174 $\pm$ 0.094*

Note: * significant difference ($p<0.05$, Student's t-test) in comparison to the initial value.

Table 3. Mineral density in a proximal tibial metaphysis ($M \pm SD$)

Period	Mineral density, g/cm ²	
	Metaphysis	Cortices
Normal value	1.571 $\pm$ 0.094	1.736 $\pm$ 0.127
Before surgery	0.705 $\pm$ 0.049	1.043 $\pm$ 0.073
After surgery		
D 30	0.854 $\pm$ 0.068*	1.172 $\pm$ 0.082*
D 60	0.874 $\pm$ 0.070*	1.211 $\pm$ 0.073*
After frame removal		
6 months	0.885 $\pm$ 0.071*	1.218 $\pm$ 0.085*
12 months	0.890 $\pm$ 0.053*	1.215 $\pm$ 0.079*

Note: * significant difference ($p < 0.05$, Student's t-test) in comparison to the initial value.

Table 4. Amount of mineral substances in L2, L3, L4 vertebrae ($M \pm SD$)

Period	Amount of mineral substances; g
Normal value	59.10 $\pm$ 4.10
Before surgery	47.30 $\pm$ 2.84
After surgery	
D 30	49.10 $\pm$ 2.71
D 60	53.0 $\pm$ 2.82*
After frame removal	
6 months	54.60 $\pm$ 2.64*
12 months	54.80 $\pm$ 3.12*

Note: * significant difference ($p < 0.05$, Student's t-test) in comparison to the initial value.

CONCLUSION

Thus, we can remark, that combined techniques of osteosynthesis with application of bioactive implants used in patients with osteogenesis imperfecta for limb deformity correction enable to achieve a secure orthopedic outcome: correction of both angular and torsion deformities in femur and tibia simultaneously. Duration of external fixation does not exceed 1.5-2 months. Combined osteosynthesis used at the beginning of treatment in deformity correction becomes the intramedullary one after removal of the external fixator and prevents deformity relapse.

Combined osteosynthesis allowing to weight-bearing on the operated limb and mobilization of patients from first postoperative days allows to preserve and even to increase bone mineral density. First, this effect results from an early verticalization of patients and correspondingly an early weight-bearing on operated limbs. The second important element is HA-coated intramedullary nailing. Hypothetically, applying it, we can suggest an effect of decreasing or even excluding of mobilization of skeleton calcium repository (of intact and operated bones). The third factor is biointegration of implants [48,50]. It provides an increased stability of osteosynthesis of bone fragments, which advances bone consolidation and frame removal. All together these factors promote motion activity of a patient, necessary for preserving skeletal mineral density.

Chapter 6

USE OF INTRAMEDULLARY BIOACTIVE NAILING IN DEFORMITY CORRECTION IN PATIENTS WITH X-LINKED HEREDITARY HYPOPHOSPHATEMIC RICKETS

Arnold Popkov*, PhD, MD

Scientific and Clinical Laboratory for Deformity Correction
and Limb Lengthening, Federal Russian State-Financed Ilizarov Scientific
Center for Restorative Traumatology and Orthopaedics, Kurgan, Russia

ABSTRACT

Introduction. X-linked hereditary hypophosphatemic rickets (XHPR) is the most common form of the hypophosphatemic rickets caused by renal phosphate wasting. The operative procedures to correct multiplanar bone deformities may be indicated for prevention of secondary orthopedic complications.

The aim of this retrospective study was comparison of results of correction in short and long term follow-up in children with XHPR who underwent the treatment with either the Ilizarov device alone or a combined technique consisting of the Ilizarov fixator and FIN.

Material and methods. We retrospectively analyzed 47 cases of surgical treatment in children affected by XHPR. Simultaneous deformity correction in femur and tibia was performed with the Ilizarov device (group I) or the combined method (group II).

Results. A monofocal bisegmental transosseous osteosynthesis was performed in group I on 24 limbs, a polyfocal bisegmental transosseous osteosynthesis was performed in 20 cases. In group II the monofocal polysegmental transosseous osteosynthesis was performed in 30 extremities, the polyfocal bisegmental – in 20 limbs.

The duration of external fixation was noted to be considerably shorter applying the combined technique: 124.7 ± 14.9 days (group I) vs 87.4 ± 13.2 days (group II).

In both groups deformity correction was achieved with a proper alignment and normal orientation of the knee joint. Nevertheless, while a child keep on growing in long

* Corresponding Author's Email: apopkov.46@mail.ru.

term follow-up, deviations of the mechanic axis from the center of the knee joint have been developing again and values of mLDFA, mMPTA have become pathologic in the most of cases. In group I location of a newly developed deformity resembled to a preoperative one, i.e., both, diaphyseal and metaphyseal parts were deformed. It is worth of mentioning that in group II in all the cases an apex of deformity (CORA) was located in distal metadiaphyseal zone of the femur and proximal metadiaphyseal zone of the tibia. It is important that all of them in group II were out of zone of the intramedullary nail tracks, in other words it is possible to prevent deformity recurrence with FIN.

Conclusion. The deformities of lower limbs in children with XLHR should be operatively corrected. Application of a combined osteosynthesis allows to considerably reduce the duration of external fixation, decrease the number of infectious complications, avoid secondary displacement of fragments. There were no recurrent deformities in parts of bone reinforced by intramedullary nails.

Keywords: X-linked hereditary hypophosphatemic rickets, combined surgical technique

INTRODUCTION

X-linked hereditary hypophosphatemic rickets (XHPR) is the most common form of the hypophosphatemic rickets caused by renal phosphate wasting, impaired renal production of 1.25-dihydroxyvitamin D3 and abnormal bone mineralization [1,2,3]. Clinical orthopedic features become obvious since the beginning of ambulating and are manifested by varus or valgus deformities of the lower limb, torsion deformities, impaired gait, short stature, pathologic fractures [2,4,5,6]. The conservative treatment is not always successful. In such cases, operative procedures for correction multiplanar bone deformities may be indicated to prevent secondary orthopedic complications like pain, pathologic fractures, degenerative arthropathy; or for cosmetic reasons [7-9].

Patients with deformities have been treated by various methods of corrective osteotomy and fixation devices, such as Kirschner wires, plates, temporary epiphysiodesis, Ilizarov devices and intramedullary nailing devices [8,9-12]. Different problems related to surgical correction were reported, among them increased rate of non-union after osteotomies, delayed union, recurrent deformity, deep intramedullary infection, refracture, nerve palsy and pin tract infection [13-15].

In our opinion, the Ilizarov method remains the most efficient technique from the point of view of multi-planar and multi-apical deformity correction. Application of a circular external device is crucial for orthopedic surgeons in particular [8,11,12]. A combination of external fixation and intramedullary rigid osteosynthesis allows to reduce the period of external fixation [13]. Nevertheless, in pediatric practice such combination is not applicable; on the other hand, the deformity correction should be performed in childhood in order to prevent development of early arthrosis.

Results of deformity correction were compared in two groups of patients differentiated by use of the external fixator alone (group 1) and application of the combined technique (external fixator and intramedullary nails with bioactive coating, group 2). Criteria of comparison were efficiency of the procedure, duration of external fixation and occurred complications.

MATERIALS AND METHODS

We retrospectively analyzed 47 medical charts of children affected with XHPR and hospitalized for correction of developed deformities of the lower limb. Criteria of inclusion were: deformities of two segments (femur and tibia) on both limbs, age under 18 years old, simultaneous deformity correction in femur and tibia on one limb with the Ilizarov device (group I) or the combined method (the Ilizarov device and intramedullary nailing – group II).

Diagnostics of all the patients was based on the typical laboratory finding of hypophosphatemia, elevated alkaline phosphatase activity in combination with presence of limb deformities, low stature and beginning of deformity development in average at 2-year-old age.

All the children received adequate oral phosphate and calcitriol therapy. In all the cases drug-resistant deformities were detected, which induced the lower limb deformities requiring operative correction [9].

Criteria of assessment were as follows:

- mechanical axis deviation (MAD), mechanical lateral distal femoral angle (mLDFA), mechanical medial proximal tibial angle (mMPTA), angulations at a level of femoral and tibial diaphysis [15,16], torsions;
- type of operation, number and levels of osteotomies, immediate or gradual character of corrections;
- duration of the external osteosynthesis;
- complications, their outcome;
- classification of results according to Lascombes [17] was used in 10-12 months after treatment.

Weight bearing full-length anteroposterior radiographs of the entire lower extremities were taken in a standing position with the patella centered forward, and lateral radiographs of each segment with adjacent joints were obtained. Radiologic indices (MAD, mMPTA, mLDFA) were measured preoperatively, after frame removal and in 10-12 months after treatment.

Surgical correction procedures were planned according to the patient's clinical assessment and radiographic data. Principles of deformity correction with the Ilizarov fixator considering CORA and ACA were strictly respected in all cases [12,16]. Taking into consideration systemic involvement of limbs, i.e., there were no intact limb for reference in planning of the correction gain, the average statistic radiologic values normal for the age were used [15].

The first surgical step was standard in both groups: it consisted of application of the external fixator, followed by percutaneous osteotomies. Frame assembly (rings and half-rings), position of olive wires and hinge elements were dictated by anatomic location and severity of the deformities in both groups. If the deformity was located at only one level of the bone segment, one single osteotomy was performed through a 10–15 mm longitudinal incision centered over the metaphyseal, metadiaphyseal or diaphyseal region. If the deformities were more severe, the double percutaneous osteotomies were done. In tibia the osteotomy of the fibula was performed in the lower third or between the middle-lower thirds

of the shaft. In all the cases the operation was performed on both segments of the lower limb simultaneously under one general anesthesia.

In group II the second step was FIN with chitosan-hydroxyapatite (HA)-coated titanium nails. In cases of monofocal correction two entry holes at metaphysis level were created with an awl in an oblique direction toward the osteotomy, at some distance from the growth plate. We recommend to select the closest metaphysis to the osteotomy in order to facilitate insertion of the intramedullary nails and proper orientation after intraoperative correction. The 1.8–2 mm nails were contoured to achieve a curvature of about 50–60°. Nails must be carefully advanced one at a time following the natural bow of the diaphysis, pushed across the osteotomy site and directed to the opposite metaphysis. After the nails have been inserted, they were reoriented so, that their concavities were oriented toward the convexity of the deformity. Once the nails were in place, the deformities were immediately corrected - totally or partially depending on the angulation. Generally, the acute total correction was used in deformities inferior to 30°. Obviously, a proper FIN construct facilitated realignment and prevented undesirable displacement of bone fragments. The free ends of nails were bent outside the bone to prevent migration during realignment. Then, they were trimmed, leaving approximately 5–10 mm from the bone surface. The skin was closed in one layer.

In cases of bifocal correction of a complex deformity, bipolar combined FIN was more appropriate. The intramedullary nails were inserted towards each other from opposite metaphyses. This principal of FIN positioning was used in diseases associated with extreme bone fragility or in bifocal limb lengthening [18,19]. Insertion and orientation of intramedullary nails were performed according to the above mentioned steps.

Finally, the additional wires/half-pins were inserted with the FIN construct in place: in the proximal and distal rings (short arches) and/or some middle-ring wires in bifocal correction.

Corrections of angular and rotational deformities were performed either in the acute or the gradual setting, depending on the severity of the deformity. Deformities of 30° and more were corrected partially at once, residual deformities – gradually. In case of gradual correction the lengthening of 1-2 cm was gained. Gradual correction can be initiated on the 5th postoperative day. In all cases we strived to eliminate the present deformities and to prevent under- or overcorrection, which is known to be fraud with relapse of deformations [7,10]. Once the external fixator has been removed, regenerates remained protected by at least one intramedullary nail in group II. In all the patients of group II the intramedullary nails stayed in their place for the whole follow-up period. By the end of operative treatment all the patients continued receiving oral phosphate and calcitriol therapy.

RESULTS

The mean age of patients in group I was 10.7 ± 2.4 years, in the group II - 8.9 ± 2.1 years. In both groups varus limb deformity was more frequent: 40 limbs in the first group and 46 – in the second. Valgus deformity was faced only in 4 patients, 2 in each group.

Considering the location of deformities, the monofocal bisegmental transosseous osteosynthesis (one osteotomy of femur and one of tibia) was performed in group 1 on 24 limbs, a polyfocal (double osteotomy of at least one of the segments) bisegmental

transosseous osteosynthesis was performed in 20 cases. In group 2 the monofocal polysegmental transosseous osteosynthesis was performed on 30 extremities, polyfocal bisegmental – in 20 limbs (Figures 1 and 2).

Duration of the external fixation period with the traditional Ilizarov technique vs HA-coated titanium nails is presented in Table 1. It is obvious that the duration of external fixation in group 2 was considerably shorter, which can be explained by stimulation of bone formation by means of bioactive implants in the osteotomy site [26-28].

Table 1. Duration of the external fixation (days)

	Group I	Group II
Varus deformity of lower limb	124.7±14.9	87.4±13.2*
Valgus deformity of lower limb	137.8±13.6	111.3±7.4*

*Significant difference ($P < 0.05$, Student t test) in comparison with the group I.

Table 2 presents values of MAD, mL DFA, mMPTA before treatment, after frame removal, by the beginning of weight-bearing and in a year follow-up.

In both groups deformity correction was achieved with a proper alignment and normal orientation of the knee space according to mechanic axes of segments. The results of correction remained preserved during the first year after treatment.

Table 2. Values of MAD, mL DFA, mMPTA

		Before treatment				At the beginning of full weight bearing after frame removal				In 10-12 months after frame removal			
		MAD	mL DFA	mMPTA		MAD	mL DFA	mMPTA		MAD	mL DFA	mMPTA	
Group 1	Initial varus deformity of limb	40.8±9.95	100.5±3.8	77.7±3.5		0.9±4.0	88.2±1.6	89.3±1.7		11.5±5.3	92.5±11.3	88.1±7.3	
	Initial valgus deformity of limb	39.8±4.1	68.5±2.6	103.3±3.5		5.1±0.96	89±1.8	92±1.6		6.7±3.1	8.9±7.5	91.3±5.3	
Group 2	Initial varus deformity of limb	40.2±9.2	100.4±3.9	77.1±3.8		0.7±3.9	88.6±1.6	89.3±2.1		4.9±8.2	90.1±6.1	89.1±7.9	
	Initial valgus deformity of limb	42.5±4.9	67.3±1.7	106.3±3.1		3.3±1.3	88.3±0.5	89.8±0.96		5.6±2.9	87.3±7.5	89.6±10.2	

The following complications were observed in group I: pin track infection in 24 cases (in 4 cases it required changing of wires under general anesthesia); transient sciatic or peroneal nerve palsy - 6 cases; displacement of bone fragments in postoperative period requiring adjustment of the Ilizarov fixator under general anesthesia – 8 cases; in 2 cases a plastic deformity at a level of correction occurred during the first week after frame removal, it required redressment of the deformity under general anesthesia and immobilization in a new plaster cast. In group II pin track infection was noted in 16 cases (in two cases wires were removed and reinserted); 7 cases of sciatic or peroneal nerve palsy with complete regression; in two cases intramedullary nails were insufficiently cut off and their free ends irritated soft tissues.

Figure 2. (Continued).

Figure 2. A 17-year-old boy with hypophosphatemic rickets. Before surgery: clinical appearance (a); AP X-rays, illustration of preoperative planning, defining CORA and ACA (axis of correction of angulation, marked X) (b); Ilizarov fixator in place for multisegmental correction of the left lower limb: clinical appearance and, X-rays, duration of external fixation 91 days (c); clinical appearance et X-rays 1 year after removal of the external fixator (left side) and before surgery of the right lower limb (d); Ilizarov fixator in place for multisegmental correction of the right lower limb: clinical appearance and, X-rays, duration of external fixation 97 days (e); clinical appearance and X-rays 1 month after frame removal (f).

Thus, the results in group I were classified according to Lascombes [18] as follows: category I in deformity correction – 30 extremities, IIa – 12 limbs, IIb – 2 limbs. In group II : I – 46 limbs, IIa – 4 limbs. It is worth of mentioning that complications with sequelae (III, IV categories) were not observed in any patient of both groups.

DISCUSSION

Orthopedic complications of the X-linked hereditary hypophosphatemic rickets - severe deformities of lower limbs – develop in young age, so indications for operative treatment appear rather early [2,5,20]. Series of studies were published describing performed surgical treatment even when a patient's resistance to conservative treatment was stated [5,8,10]. Studies revealed that excess of fibroblast growth factor 23 action results in hypophosphatemic disease because it suppresses the expression of sodium-phosphate cotransporters in the proximal tubules of kidneys, which mediate physiological phosphate reabsorption [21-23]. Imel et al [3] discovered a significant increasing of circulating FGF23 concentrations while phosphate and calcitriol therapy, which can be a cause of resistance of patients with X-linked hereditary hypophosphatemic rickets to conservative treatment.

The developed deformities of lower limbs should be surgically corrected in order to maintain normal biomechanic conditions for ambulating, for cosmetic reasons and to prevent early severe arthrosis of hip and knee joints [12,13,23].

Various methods are used for fixation of bone fragments after performed osteotomies as plaster cast, K-wires, bone plates, external fixators, intramedullary nails [4,5,7,9,10,12]. It goes without saying that application of intramedullary locked nails in pediatric orthopedics is restricted.

Circular devices of external fixation with parallel or hexapodal position of connecting rods [8,11,13] provide the best conditions from the point of view of accuracy of deformity correction, abilities of gradual controlled correction of all deformity components in a postoperative period at a level of femur and tibia simultaneously, absence of interference in growth cartilages, absence of inhibition of the following segment growth in length.

In our study in both groups of patients the required correction was achieved simultaneously in femur and in tibia using the Ilizarov fixator and principles of Ilizarov method. Difference between the groups was in duration of fixation, number and severity of complications.

A general problem of external fixation remains a long period of fixation: from 4 months or 146 days in average [8,11] to 6 months [7]. There is a possibility to reduce considerably the duration of external fixation reported by Kocaoglu et al [5]. The external device was removed either after acute correction and introducing the intramedullary nail or by the end of distraction period. That approach allowed to reduce the duration of external fixation considerably, to prevent recurrent deformities and to preserve the accuracy of correction peculiar to application of circular fixators [12,13,15]. But the application of locked intramedullary nails is inadvisable in children and it requires another approach.

Considering advantages of FIN [18,19,24], we applied this type of osteosynthesis with elastic intramedullary nails coated with a bioactive layer in children affected by XHPR, who underwent acute correction on femur and tibia. It allowed to decrease the mean duration of external fixation to 87.4 days in deformity correction in varus limb axis and to 111.3 days in valgus limb axis (in average by 37 and 26 days correspondingly).

A prolonged period of external fixation can be associated with a high risk of complications. Petje et al [8] reported about one episode minimum of infectious complication around wires or half-pins in every patient while deformity correction with an external fixator. Song et al [13] noted in 20 patients 18 major complications (recurrent deformity, fracture

after frame removal, peroneal nerve palsy) and 13 minor complications. In the series of Fucetese et al [7] development of contractures of the knee joint and infection were observed.

In our study the FIN application allowed to decrease infectious complications and to avoid any secondary displacement of bone fragments during gradual correction, fractures and deformities at the level of correcting osteotomies after removal of external fixators. No complications concerning migration of intramedullary nails with bioactive coating were also noted.

In general, a high rate of deformity relapse is observed during the long term follow-up after operative correction in children with this pathology. Song et al [13] observed complications (recurrent deformity or fracture at a level of correction) in 10 patients out of 21, Rubinovitch et al [4] reported relapse of deformity in 27% of cases. Petje et al [8] observed up to 90% of recurrent deformities after primary correction and up to 60% after secondary surgeries, besides the rate of relapses reduced after the age of 14 years old. There is no data yet of development or relapse of the deformity of lower limbs in long term follow up (5-7 years) after surgical correction of deformities in children with XHPR and after the end of natural growth. It requires a longer period of follow up.

CONCLUSION

Nevertheless, advantages of combined osteosynthesis (circular external fixator and FIN with bioactive coating) can be already stated as shorter duration of external fixation, decrease of infectious complications and absence of secondary displacement of fragments during correction or deformities at the osteotomy level after frame removal.

Federal Russian State-Financed Ilizarov Scientific Center for Restorative
Traumatology and Orthopaedics, Kurgan, Russia

ABSTRACT

Chapter V is a review of contemporary techniques of osteosynthesis of the spine. Advantages and disadvantages of modern internal systems of spinal correction and fixation are assessed, variants of combination of external and internal osteosynthesis of the spine are presented. There will be demonstrated variants, methodology and advantages of state-to-art methods of external spinal fixation and combined approaches associating merits of the external fixation and Cotrel-Dubousset systems. Abilities and advantages of the technique are analyzed and clinical observations with analysis of efficiency of correction are presented.

Keywords: combined technique, spine surgery

INTRODUCTION

Spinal deformity is one of the most frequent and leading syndrome of complex vertebrogenic pathology, congenital anomalies of vertebrae and ribs, systemic and neuromuscular diseases, posttraumatic modifications, idiopathic scoliosis and often their combination. The most important features of spinal deformity are the rate of progression and amount of deformity. These same features influence on cosmetic and functional outcome and, as a result, on quality and length of life.

* Corresponding Author's Email: rso_@mail.ru.

Surgical treatment of patients with a spinal deformity is supposed to solve the following problems: to stop deformity progression, to perform its maximum possible correction and to provide conditions for preserving the result. Despite of various manifestations of the disease, patients with spinal deformities are united by one common group of problems, they are variability of neurologic deficit, body balance disorder, persistent progression, functional degradation of cardiopulmonary system, unsatisfactory appearance and low quality of patients' life [2, 7, 8, 9]. Surgical treatment of patients with deformities over 100° is characterized by a high intraoperative risk and a high rate of complications in the postoperative period [2, 9, 10, 11].

All the methods used for spinal deformity correction can be subdivided in 2 groups: basic techniques, i.e., standard techniques of acute correction using widely spread implants; hybrid approach, i.e., combination of mobilizing methods (variants of traction and methods of vertebrotomy) with methods of distraction, derotation and reclination (in kyphosis) by means of external and internal fixation devices.

This chapter deals with indications and techniques of external fixation in children and adults, their combination with methods of spine mobilization in severe deformities and internal instrumental fixation. In severe forms of idiopathic scoliosis in children it is conventional to use tactics of preliminary traction for spine deformity correction, cranio- or halo-pelvic traction or traction with external fixation systems. Application of methods of preoperative halo-traction allows manipulating the major deformity arch indirectly by means of the most mobile spine regions, that considerably reduces this influence [3, 11]. Systems of external transpedicular fixation remain applicable, they possess mechanical advantage from the point of view of application of corrective efforts to major deformity arch while gradual correction, preserving patient's mobility and monitoring of neurologic and somatic status of the patient [1, 4, 5, 6, 10].

Despite many unsolved problems for the moment, we have tried to disclose the author's view on tactical issues of surgical treatment, such as possibility to perform simultaneously a neurosurgical and vertebrologic stages, a type of fixation, its extension, indications and techniques of combining of instrumentation methods, indications and application possibilities for corrective and shortening vertebrotomies. Also, the treatment outcome and complications are analyzed.

METHODS OF EXTERNAL FIXATION

Halo-Pelvic System

One of the most expanded types of spinal external fixation is halo-pelvic traction. The method is widely used for correction of severe spinal deformities of any etiology, including atypical (cervical and cervical-thoracic) locations. In our practice, we use this technique independently. The technique is applied as a variant of traction during the first stage of surgical correction, it is also combined with methods of mobilization of the major arch. The second stage is transpedicular fixation of the spine. Besides, this technique is used as a variant of a "lifeboat" in pressure sores at the apex of kyphosis of any etiology. The variant of

extrafocal fixation allows to create a reserve of soft tissues for wound healing by means of stabilization and distraction efforts [3].

Figure 1. Patient's image after deformity correction by Ilizarov halo-pelvic system.

The halo-pelvic device is assembled of Ilizarov set components (Figure 1) or the module halo-pelvic apparatus is applied (Patent RF utility model N 124137 dtd 20.01.2013) (Figure 2).

Figure 2. Halo-pelvic apparatus of the module type.

The device is applied to the patient lying in the supine position under general anesthesia with. Primary distraction for construction tension is performed on the operating table. Then starting from the 2nd day of the postoperative period the distraction along the axial rods is administrated at the rate of 0.5 cm per day within 7-21 days. Dressing with monitoring of wounds is performed in two days. The time of traction is determined empirically according to rigidity of the deformity and degree of the device tension. The traction longer than 3 weeks is not recommended because of the risk of infection complications. During the distraction period the patients can take care of themselves independently, clinical control of neurologic and somatic complications is extremely important. If the latter ones occurred, the distraction efforts are reduced by 1-2 cm following by dorsal transpedicular fixation.

Device for the External Transpedicular Fixation

This type of external fixation is used in spinal deformities over 100° of thoracic and lumbar location, as well as in inflammatory processes of soft tissues of the back on the background of unstable lesions of vertebrae [5, 6]. It is not used independently, it is applied as a traction technique to prepare to dorsal instrumental fixation.

The surgery is performed under narcosis with the patient in the prone position. The frame assembling depends on the amount and 3D orientation of deformity arches. Threaded rods are inserted by pairs into the vertebra arch pedicles through the micro incisions up to 0.5 cm. They form support units (Figure 3a). Every unit contains 3-4 segments depending on anatomical features of the patient's spine. If fixation of the pelvis is required, two pairs of threaded rods are inserted in the wings of iliac bones bilaterally.

Figure 3. Assembling stages of the device for external fixation in severe idiopathic scoliosis (Lenke 3C+): insertion scheme of Schantz screws (a), connection of support units (b).

Then units are connected with longitudinal rods. Partial acute correction of the spinal deformity is performed on the operating table followed by antiseptic dressing (Figure 3b). Maximum possible correction of the spine is achieved during the postoperative period with monitoring of the neurologic status and X-ray control.

Dressings are changed every 3rd day. By the end of 10-14 days of correction in the frame at the rate of 0.5 cm/day the final open transpedicular instrumental correction and fixation of achieved spinal deformity correction is performed simultaneously with formation of posterior spondilodesis. This technique provides good and satisfactory treatment results (correction over 70%) minimizing the risk of neurologic and somatic complications.

External Transpedicular – Pelvic Fixation

Combined technique is also used as a lifeboat technology in inflammatory processes of soft tissues at the deformity apex of the lumbar spine. The technique unites advantages of transpedicular spinal fixation with pelvic screw fixation and localizes mechanical efforts in the lumbar department. Besides, the technique can be used as preparation for the major stage of correction.

Figure 4. External transpedicular-pelvic fixation as a method of extrafocal fixation for pressure sore healing at the apex of deformity in congenital kyphosis on the myelocèle background in a 9-year-old female.

The surgery is performed from a dorsal approach. Administration of narcosis and assembling of units don't vary. A distinctive feature is assembling of a transversal rod between pelvic units and their connection by two longitudinal rods with a spinal unit. It allows to build a united trapeze of rigidity (Figure 4). Dressing mode and distraction rate are the same.

COMBINED METHODS

Combination of Halo-Pelvic and Posterior Instrumental Fixation

“Connector”- type systems are used in actively growing children. This method is favorable for patients with severe spinal deformity and high risk of somatic and neurologic complications [11]. The external fixation is aimed to control somatic and neurologic status.

Let us review this technique on the example of a patient with severe progressing cervical-thoracic scoliosis in systemic pathology, who has not received an adequate well-timed orthopedic care for a long period. By the age of 11 he was already affected by serious statodynamic and functional disorders, which impair his life quality and even threaten his life. Obviously, the very patient’s existence was challenged without solving the orthopedic problem.

The male patient, 11 years old, was first seen for spinal deformity by a spinal surgeon in July 2011. The anamnesis revealed that the patient has been followed by an orthopedists since the age of one, when the deformities of limbs appeared. He was administrated a conventional treatment as massage of limbs and orthopedic shoes. The diagnosis of Ollier disease was verified by geneticist in 2001. The spinal deformity has been persisting for the last 2 years. Orthopaedic status showed disproportionate stature, evident cachexia with a weight of 18 kg, decompensated rigid extended right-side cervico-thoracic scoliosis with deviated torso to the right and head to the left up to 90° of Cobb’s angle, gibbus on the right, hypertrophic muscles of the neck being more severe on the right, clinodactyly and hypertrophied phalanges of the fingers, and grade I funnel chest deformity (Figure 5a,b). The traction test proved apparent rigidity of the deformity. Minimal exercise (walk up to 20 m distance) caused growing respiratory insufficiency. The lower limbs muscle strength in neurologic status was reduced to 3 according to ASIA score. No sensory impairment and pelvic organ dysfunction were detected. The patient developed quick fatigue with episodes of hypoxia (falling asleep).

Figure 5. (Continued).

Figure 5. Image and data of X-ray investigation of the 11-year-old patient: photo of the patient in the intensive care unit: clinical torso deformation and cachexia (a), photo and X-ray of the left hand (b), X-ray of the spine (c), CT of the neck and thorax, Volume Reformation Tomography: severe rotation of cervical vertebrae (d), CT of the thorax, axial plane: signs of pneumofibrosis (e).

X-ray investigation displayed atypical spinal deformity with the apex of the major arch at the C₆-C₇ level, absence of vertebral-medullary conflict and fibrous modifications of pulmonary tissue (Figure 5c,d). Hospitalization to the Kurgan Ilizarov Center was recommended for additional assessment and considering possible surgical correction. Though, admission to the clinic was postponed because of viral respiratory infection. Emergency admission to the regional children's hospital was required on August 01, 2011 for a severe condition with complaints of spitting up blood, coughing, frequent episodes of sleep apnea up to 1 min long. Probably, the VRI caused complications of respiratory insufficiency on the background of severe restrictive lung affection. Mechanical lung ventilation, antibacterial and syndrome-based therapy were performed at the intensive care unit. The reduced mechanical ventilation parameters led to higher levels of hypercapnia.

Figure 6. Photo (a) and X-ray of the spine (b) of the 11-year-old patient after deformity correction with the halo-pelvic system using the Ilizarov set components.

The boy was examined by a team of spinal surgeons of the Kurgan Ilizarov Centre on August 05, 2011. Considering his severe syndrome of respiratory insufficiency on the background of significant decompensated scoliotic deformity, it was decided to correct the deformity by halo-pelvic device as the less invasive, simple and adequate method for stabilization of the patient's condition. External fixation device was applied for halo-pelvic traction on August 05, 2011. The frame was set up in the distraction mode of 6 cm to correct spinal deformity and create favorable conditions for lung excursion (Figure 6). The surgery lasted 35 minutes. The volume of blood loss was up to 20 ml. Saturation normalized within 24 postoperative hours. However, tracheostomy was performed due to progression of

respiratory failure on August 16, 2011. The patient's condition stabilized and he was transferred to autonomous breathing with *tracheostomy* in 2 days and transported to a somatic department in 7 days (on August 25, 2011).

The patient was referred from the regional children hospital to neurosurgery department of FSBI "Russian Ilizarov Scientific Centre "Restorative Traumatology and Orthopaedics" on September 27, 2011. The diagnosis on admission indicated the Ollier disease with multiple deformities of axial skeleton, severe combined scoliosis with underlying systemic pathology and disturbed cervical spine formation, progressing muscular dystrophy, pneumofibrosis of the right lung, myocardiodystrophy, grade 3 cachexia, tracheostomy, condition after frame application for halo-pelvic traction.

On admission to the Centre the patient was able to stand independently for 10 minutes and walk with a support for 6 minutes without respiratory imbalance, and he needed help with his meals and getting up. His torso balance improved in the coronal plane with persisted decompensation, but sagittal balance was compensated (Figure 6a). Deformity correction in the frame was observed at the level of major cervical-thoracic arch up to 32° (-31°), at the level of minor lumbar arch - 10° (-2°) (Figure 6b). Spirometry revealed decrease of lung capacity to 43%.

Operative intervention performed on September 29, 2011 included correction and multi-support instrumentation fixation of C₂-Th₉ segments with combined connector-type system, posterior local spondylodesis, dismantling halo-pelvic traction system (Figure 4). Loss of blood volume was 200 ml (5% of the total blood volume).

Satisfactory functional and cosmetic effect was obtained (Figure 7). Functional result assessed in a month after the surgery showed increased vital capacity of 56% according to spirometry findings and improved respiratory function with pulmonary stress test. The patient could walk with a support during 30 minutes without respiratory imbalance, eat food and stand up by himself, with torso balance in the coronal and sagittal planes being compensated (Chapter 6, Figure 2a). The patient's weight was 21 kg (+3 kg). Checkup radiographs showed adequate screw position, spinal deformity correction achieved at the level of major cervicothoracic curve to 12° (-51°), at the level of accompanying lumbar arch to 10° (-2°) (Figure 7b). Therefore, the spinal correction was 81% and 17%, correspondingly. Neurologic assessment demonstrated positive dynamics in improving lower extremity muscular strength graded 4. The child was discharged on November 04, 2011 in 95 days after urgent hospitalization, and tracheostomy was removed on November 23, 2011.

This case demonstrates capacity of surgical orthopedic care, aimed to stabilize functional condition of the child and to improve his life quality. Absolute indications for the surgery were life threatening disorders caused by scoliosis. The halo-pelvic device was chosen because of its features as minimal surgical aggression, gradual distraction and neurologic control. Besides, we always consider this method as the method of choice for patients with severe deformities in life threatening conditions as demonstrated in the previous case. When somatic status is stabilized, the spinal departments are fixated with posterior internal multi-support system. This strategy is substantiated by severe functional disorders, related to major disease as well as to spinal deformity and high risk of neurologic and vital complications caused by its correction.

Figure 7. Photo (a) and radiographs (b, c) of the patient prior to discharge. Major arch of the deformity corrected to 12° .

Method of 4-staged correction are performed in two surgeries. The first surgery is anterior multilevel vertebrotomy, formation of interbody spondylodesis, closed osteosynthesis with external transpedicular fixator. The second surgery is Smith-Petersen osteotomy, correction and stabilization of the deformity with a transpedicular system forming posterior spondylodesis.

Aggressiveness of this technique determines the spectrum of its application – extremely severe spinal deformities of any etiology (scoliotic deformity with Cobb angle over 100° , Aaro-Dahlborn apical torsion over 60° , mobility of the major spinal deformity curve according to functional X-rays not exceeding 5% of the initial deformity) associated with progressing functional, neurologic and static-dynamic deficiency. Potentially, indications for the surgical treatment for those patients are vital, because of dramatic impairment of functions (especially the function of external respiration – FER). Surgical interference is based on the low-invasive principal for the segment being operated as well as for the organs involved in the surgical approach. That is why posterolateral thoracotomy and transpleural approach are not used in this group of patients. It can cause lungs collapse and turn severe FER deficiency into irreversible.

Figure 8. Apex of the major deformity arc after extensive anterior release.

The first stage is performing of an extensive anterior release at the level of 4-7 vertebrae-mobile segments of a concave side of the deformity apex, similar to anterior multilevel osteotomy at 270°. It differs from a standard technique of anterior release by an incision, which is performed parallel to the major arch along the posterior axillary line. It is convenient, as a severe torsion forms “vertebral” pleural sinus with no pulmonary tissue. After exposing posterior rib complex, 5-6 rib sectors are excised from midaxillary line with exarticulation of ribs, it provides effect of mobilization by decreasing rigidity of the thorax and a cosmetic effect at the same time. Then, extrapleural or transpleural approach to the vertebral bodies is performed. It is important to exclude a direct contact with lungs. Excision of intervertebral disks and epiphyseal plates is followed by a wedge adaptive resection of apical 4-7 vertebral bodies to correct their wedge shape. Anterior and posterior longitudinal ligaments are resected with visualization of the dural sac at 4-7 levels (Figure 8).

The second stage of the first surgical session is application of the external transpedicular fixator (Figure 9). In 10-14 days by the end of correction, a posterior extensive Smith-Petersen osteotomy at the deformity apex, application of transpedicular screws are performed followed by corrective maneuvers. The procedure is ended by formation of the posterior bone-plastic spondylodesis.

Combination of external fixation methods (halo-pelvic, external transpedicular fixation device) with variants of corrective vertebrotomy (spondylectomy through the root of vertebral arch or VCR), correction and posterior instrumental fixation of the spine, 360° bone graft spondylodesis.

Indications for this technique are deformities of a severe and extremely severe degree complicated with inflammation of soft tissues (Figure 9a,b).

The first stage is removal of implants from a dorsal approach, if necessary, wound debridement, stabilization with external fixation systems (halo-pelvic, external transpedicular fixation device, external transpedicular fixation – pelvic device) (Figures 9c, 10c) aimed to extra-focal correction stabilization of the deformity. Extra-focal external fixation provides favorable conditions for healing of soft tissues. The second stage is performed when the wound is healed. Its volume depends on the amount of deformity, its rigidity, neurologic deficiency. In our practice the second stage varied from the posterior instrumental correction and stabilization to VCR vertebrotomy (Figures 10 and 11).

Figure 9. X-rays of a 14-year-old patient with typical idiopathic kyphoscoliosis of an extremely severe degree (Lenke 3C+): before treatment, scoliosis Cobb - 132° , kyphosis Cobb - 145° (a, b), in external fixator after anterior multilevel osteotomy (c), after removal of external transpedicular fixator, posterior extensive Smith-Petersen osteotomy at the Th₇₋₁₁ level, correction, posterior instrumental fixation and posterior spondylodesis: scoliosis Cobb - 64° , kyphosis Cobb - 82° . Correction rate is 52% and 45% correspondingly (d, e).

Figure 10. (Continued).

(g)

Figure 10. Photo and X-rays of a 22-year-old male patient. Spinal cord injury, late period. Sequelae of Th₁₁ burst fracture-luxation with spinal cord compression. Lower spastic paraplegia. Disfunction of pelvic organs. Post-operative condition. Complications: Unstable construction. Infection of postoperative wound: patient's photo at admission (infected pressure sores in projection of screws) (a,b), X-rays at admission (c), Image of the patient after the 1st stage of treatment (removal of implants, wound debridement, stabilization in ExTrFix device (d), surgical steps of corrective shortening vertebrotomy with a block (e, f), X-rays after surgical treatment (g).

RESULTS

Spinal surgery using external fixation is “a surgery of complications” as it is aimed to cure complicated process of spinal column deformities. Basic indications for use of external fixation techniques are extremely severe spinal deformities (Table 1) and local wound process.

(a)

(b)

Figure 11. (Continued).

Figure 11. Photo and X-rays of a 9-year-old female patient with congenital kyphosis in myelocoele with infected pressure sore at the deformity apex (a), 3D CT Volume Reformation Tomography of the spine in sagittal plane: myelodysplasia, dysraphy with hypogenesis of the posterior column and secondary structural wedge transformation of lumbar vertebral bodies (b), application of ExTrFix – pelvic device for wound healing by means of extrafocal fixation (c, d), surgery (e) and X-rays after corrective vertebral surgery and posterior instrumental fixation (f, g). Deformity correction of 84%.

Table 1. Influence of the deformity amount on the choice of a method of surgical treatment in scoliotic and kyphoscoliotic deformities of severe and extremely severe degree

Amount of deformity	Surgery		
	Mobilization	Correction	Fixation
70-100° * Mobile	- No - Smith-Petersen Osteotomy	Correction and Posterior Instrumental Fixation (PIF)	
70-100° * Rigid	- Anterior open or endoscopic release - Smith-Petersen Osteotomy	Possible Traction with ExTrFix or halo-pelvic device	PIF
Over 100° *	- Anterior multilevel osteotomy - Pedicle Subtraction Osteotomy - Vertebral Column Resection - Smith-Petersen Osteotomy	Traction with ExTrFix or halo-pelvic device	PIF

* EMG control is obligatory.

Though, analyzing the structure of complications in application of hybrid techniques, three groups can be distinguished: wound infection, implant instability and neurologic complications. Despite the external fixation, cases of wound infection in the structure of surgery of severe spinal deformities varied within the limit of 5%, which reflects average number of general surgical complications. Instability of construction, provoked by the bone resorption, despite its rareness was more often observed in young patients. It can be explained by bone-cartilaginous model of vertebrae and pelvis. Malposition and fracture of screws were in correlation with the scoliosis degree and torsion amount and ranged within 5-9%. Use of combined techniques in spinal deformity surgery allowed to decrease the rate of severe neurologic complications from 40% to 7%. It can be concluded that the method has average but controlled rate of complications.

DISCUSSION

Choice of tactics for correction of the spinal deformity of a severe degree is defined by mobility of arches. If deformities are rigid in any plane, many authors recommend mobilization of anterior and posterior departments in combination with external traction [3, 4, 6, 11].

Several authors tend to use external fixators. As major advantages the authors highlight possibility of a gradual, controlled correction, both, an isolated one followed by inversion to internal fixation and an associated one combined with anterior release at the deformity apex [3, 10, 11]. Nevertheless, this method is quite demanding to a close technique of screw insertion, biomechanically substantiated design of fixator and postoperative control [1, 3, 4, 10].

CONCLUSION

Planning of surgical treatment of spinal deformities is very individual. If spinal deformities are complicated with soft tissue inflammation at the deformity apex or there are severe functional disorders, indications for surgical treatment should be considered as vital and hybrid treatment methods must be applied using external fixation systems stage by stage.

ABSTRACT

This chapter presents the results of an experimental study of the Ilizarov external fixation combined with intramedullary nailing in the management of long bone nonunions accompanied by anatomical shortening. These results were used in clinical practice. Combination of external fixation and nailing showed to be efficient in regenerate formation and nonunion healing in experimental settings that was proven by radiographic and histological studies. In clinical settings, such an approach to patients' rehabilitation was also efficient in achieving orthopedic goals and in reduction of in-patient treatment time.

Keywords: bone defect, nonunion, Ilizarov apparatus, nailing

INTRODUCTION

The incidence of long bone nonunions and defects due to failed fracture repair is not high. However, these complications are a challenge for orthopedic management and patients' rehabilitation [1, 2].

Management of nonunions is based on the principles that are already known. The main principles are stable fixation and compression at the docking site of bone fragments [3].

The Ilizarov method of distraction osteogenesis that is based on the use of external fixators provided the surgeons with new ways of treating this pathology [4].

However, a long period of external fixation, the bulky size of the apparatus, pin-tract infection along wires, and the necessity of multistage operative treatment are the disadvantages of the method [3, 5, 6].

On the other hand, intramedullary nailing is considered nowadays to be an optimal osteosynthesis method for the diaphysis of long bones. The technique is low invasive, provides good stability and more comfort for early rehabilitation [7, 12].

Combining the Ilizarov external fixation and nailing allows surgeons improve patient's rehabilitation and their quality of life.

Our study was aimed at revealing the biological aspects of bone reparation and the technical advantages of combining Ilizarov external fixation and nailing. It presents experimental findings and clinical outcomes of using this combined technique for bone nonunion and defect management.

EXPERIMENTAL STUDY

Materials and Methods

A canine model was used for this experiment which was carried out on eight mongrel dogs in the age from one to four years, weighing between 14 and 25 kg and whose tibia length was from 180 to 240 mm. The experiment was performed according to the requirements of the European Convention for the Protection of Experimental Animals (1986, Strasbourg).

Bone defect of the tibia was modeled in the upper third of the tibial shaft and measured 2 cm. The nutrient artery was affected and blood supply was impaired due to the defect. The next step was the mounting of the Ilizarov apparatus which consisted of proximal and middle proximal three-quarter rings and one full distal ring with wires in each of the supports that were all connected by threaded rods (Figure 1a). The gap formed between the bone fragments due to the defect modeled was reduced gradually by daily 2-mm compression with the Ilizarov fixator during one week. When the gap had been reduced to 4 or 5 mm, fixation with the Ilizarov apparatus continued for two months in order to obtain nonunion (Figure 1b).

Next, the Ilizarov apparatus was dismantled in order not to hinder nailing. Intramedullary nailing using the I-Loc system (BioMedtrix, USA) was performed through the entry point in the tibial plateau. Reaming of the medullary canal destructed the cartilaginous tissue at the nonunion level. After insertion, the nail was locked proximally.

The Ilizarov apparatus in the same assembly as for the nonunion model was applied again. Osteotomy of the distal fragment was performed. Compression at the nonunion level was produced. Distraction was initiated on the fifth day. The distraction rate was 0.75 mm per day made with six steps. Lengthening continued 28 days. Supportive compression at the level of the nonunion was carried out weekly. Average tibial lengthening achieved was $11.3 \pm 0.3\%$.

On days 7 to 10 after limb lengthening, two distal interlocking screws were inserted. Then, the external fixator was removed. The experiment was completed when radiographic consolidation was visualized (on average 45 days after completion of lengthening).

Evaluation of defect compression, nonunion, bone formation and consolidation was based on radiographic examination. Anteroposterior (AP) and lateral views were taken preoperatively, after the tibial defect was modeled, every two weeks during compression for obtaining nonunion, after osteotomy, every week during distraction, seven days after the start of fixation, and every 14 days after the external fixator removal.

Figure 1. X-ray of the tibia in anteroposterior and lateral views: a - after bone defect modeling; b - after 2 months.

Histological study was carried out with the method of light microscopy (Nikmed-5, LOMO, St. Petersburg, Russia) of celloidin histotopographic sections of the tibial regenerate callus. Microphotos were taken with the DiaMorph complex (Moscow, Russia).

All animals could bear weight on the 14th day of lengthening. There were no skin problems, implant instability or other complications. Early external fixator removal did not cause regenerated bone fracture or deformity.

RADIOGRAPHIC AND HISTOLOGICAL RESULTS

The gap had inhomogeneous structure and partial closure of the medullary canal after two months (Figure 1b). The histological study confirmed the nonunion formed (Figure 2a). The interfragmentary layer contained vascularized fibrous tissue and groups of adipose cells (Figure 2b). The medullary canal of each fragment was closed by lamellar bone end plates with fibrous cartilaginous tissue on their surface (Figure 2c). The fibrous cords in the gap were united with the periosteum. They covered the bone fragments along the periphery but separated them from each other in the center (Figure 2a).

Figure 2. Histological structure of the gap between the bone fragments at 63 days of the experiment: (a) separated bone fragments of the non-union (histotopogram, Van Gieson staining, mag.x1.5); (b) fibrous connective tissue in the gap (picrofuchsin Van Gieson staining, mag. X 25); (c) lamellar bone tissue at the end of the proximal bone fragment and fibrous cartilaginous tissue on its surface (hematoxylin and eosin staining, mag. X 40).

On day 14 of lengthening, the interfragmentary gap at the osteotomy level measured 10 ± 0.3 mm. The diastasis at the nonunion docking site was slightly visualized. In five dogs

the endosteal regenerate was 3 mm long, and the periosteal layer was 0.5 mm thick and up to 15 mm long (Figure 3a). The other three dogs had inhomogeneous regenerate structure within the nonunion diastasis. The periosteal layer was 3 mm thick (Figure 3b). Mild osteoporosis was seen in all cases.

Figure 3a, b. X-rays of the tibia taken after 14 days of tibial lengthening in the conditions of combined fixation;

From day 7 to 10 after completion of distraction, remodeling of the periosteal layer at the nonunion level started in five cases. Distraction regeneration still featured inhomogeneous structure but the cortices were undergoing formation (Figure 4a).

On day 30 after completion of distraction, the nonunion healed in six cases. Fully interconnected cancellous trabeculae were formed in the distraction gap with continuous cortices (Figure 4b). Similar condition of bone regeneration in the distraction gap was revealed by day 45 after completion of distraction in other two dogs.

On day 30 after completion of distraction, the histological study of the tissue at the level of pseudoarthrosis revealed union through hypertrophic callus (Figure 5a) with cortical continuity and interconnected cancellous bone (Figure 5b). Osteoclasts were attached to the periosteal tissue and indicated bone remodeling (Figure 5c). The endosteal tissue was presented by interspersed bone tissue and vascularised reticular tissue (Figure 5d). The endosteal area had a hollow canal after nailing. The walls of this canal consisted of fibrous tissue containing capillary vessels (Figure 5e).

Figure 4. Fragments of x-rays of the tibia: (a) combined fixation on 7th day; (b) continuity of cortices all over the tibia 30 days after lengthening.

Figure 5. Morphological characteristics of the callus formed in the defect of the tibia after 30 days of lengthening: (a) histotopogram of the regeneration callus; (b) bone tissue part of the intermediary zone between the fragments; (c) periosteal bone tissue and osteoclasts; (d) reticular tissue with areas of hemopoiesis ; (e) a layer of vascularized loose fibrous tissue on the internal wall of the canal formed by the nail. Masson staining (a), Hematoxilin and eosin staining (b-e); mag. x1.5 (a), x25 (b), x63 (c-e).

Figure 6. Histological picture of the distraction regenerate 20 days after the Ilizarov fixator was removed: (a) histotopogram; (b) part of cancellous bone tissue in the intermediary callus; (c) reticular fibrous tissue containing capillary blood vessels with hyperemia; (d) fibrous tissue; (e) osteoclastic resorption on the periosteal callus. Van-Giseon staining (a), Hematoxilin and eosin staining (b-e); mag x1.5 (a), x25 (b), x63 (c-e).

The distraction regenerate had features of a newly formed bone in the diastasis (Figure 6a). The cancellous bone tissue was in the intermediary area. The cortices were denser on the periosteal level. Bone tissue was formed of cancellous bone that contained areas of reticular tissue (Figure 6b). The periosteal callus was more pronounced on the side where the nail was closer to the cortex. On the contrary, the endosteum was more developed on the side where the cortex was at a greater distance from the implant (Figure 6a). Sinusoidal blood vessels between bone trabeculae were located both in the endosteal and periosteal tissues (Figure 6c). The medullary canal in the center was inane after nail as well as at the level of the pseudoarthrosis. The internal surfaces of the canal were presented by fibrous tissue and the external ones by trabecular bone united with endosteal bone tissue (Figure 6d). Osteoclastic resorption was noted on the periosteal callus (Figure 6e).

CLINICAL APPLICATION

Combined Ilizarov External Fixation and Nailing for Nonunion Accompanied by Limb Shortening and Segmental Bone Defects

Preoperative Planning

Operative planning does not differ much from planning other orthopedic operations. It includes an accurate study of the anamnesis, careful general and local physical examination, and radiographic study. However, several issues require special attention. Evaluation of the true bone defect is a primary point because it determines the future lengthening amount to be achieved. Bone defect includes anatomical shortening as compared with the contralateral limb, interfragmentary diastasis, and the size of bone resection at the docking site (in case it is necessary). Basing on the defect assessment, the level of osteotomy, assembly of the external fixator and the distraction regenerate length are determined. The rings for the Ilizarov fixator are chosen individually. The nail of the optimal size must be prepared in view of future lengthening. Patient's preparation and anesthesia do not differ from the standard procedures before the Ilizarov osteosynthesis [8].

Surgical Technique

Step 1

The patient is positioned supine on a radiolucent table. The pelvis may be elevated with a firm cushion to make the placement of the external fixator easier. Any implant in place after previous operations should be removed in a minimally invasive manner. The entry point for nailing is produced under the control of an X-ray image intensifier (XRII). The skin incision should be minimal (two or 3 cm). Reaming of the medullary canal can be produced both with standard or rigid reamers (Figure 7). The diameter of the latter reamer type must exceed the diameter of the selected nail by 2 mm to prevent difficulties during distraction and implant instability after external fixator removal. Insertion of the nail is performed till the level of the future osteotomy under XRII control. Osteotomy is also performed under radiographic control from a small skin incision. Upon its completion, nailing is continued in the regular manner along with the insertion of static interlocking screws into the bone fragment that is to be lengthened.

The wounds are closed in a regular manner. The insertion of wires follows. The XRII use in this case is a personal preference of the surgeon. Positioning of wires or screws is standard for each anatomical segment [9]. Wires must be drilled into the bone as far as possible from the nail to prevent possible deep infection due to skin inflammation in the postoperative period [10]. A sufficient number of wires or screws in each ring or half-ring necessary only for distraction must be inserted, as the Ilizarov fixator will be removed after lengthening. Mounting of the external fixator supports, wire fixation and their tensioning, connection of the supports with threaded rods follows. At this stage, central position of the limb axis in the frame is paramount because it determines the success of distraction in future. The operation is completed by applying aseptic dressings and radiographic control (Figure 8).

Figure 7. Rigid reaming rods. Rigid reamers may be an alternative to the standard ones in case of sclerotic obliteration of the medullary canal.

Figure 8. X-ray of the femur in anteroposterior and lateral view after step 1. Threaded rods are parallel to the bone axis and nail – optimal condition for future lengthening.

Postoperative Management and Care after Step 1

Aseptic dressings must be changed on the first postoperative day. Patient can start weight bearing and walking with crutches. On the third day after the operation, motion exercises are allowed. Distraction must start on the fifth postoperative day. The mean rate of distraction is 1 mm per day made with four steps. Radiographic checking is carried out on the tenth day of

distraction. In cases when bone fragments at the nonunion docking site have contact with each other, supportive compression (1 mm every 10 days) at this level is necessary to increase stability. In our opinion, the total time with the Ilizarov fixator on the limb should not exceed one or 1.5 months for prevention of deep infection around the implant. However, if orthopedic goals require a longer external fixation period and inflammatory skin problems appear, the solution is the use of antibiotics, wire care or even the removal of problematic wires or pins.

Step 2

Full contact of bone fragments at the docking level and limb length restoration are indications for the second step (removal of the external fixator and insertion of the distal locking screws).

Patient's preparation and positioning on the radiolucent table are the same as described previously. Preparation of the operation field must be very careful, especially for the external fixator. First of all, distal locking by a freehand technique must be performed. The number and positioning of screws are defined by the size of the bone fragment, nail design and surgeon's preferences. Type of fixation of the bone fragment which was transported is a specific choice for every case. Different techniques are used: plating, cerclage suture or a locking screw placed into a special hole in the nail [11]. The first and second variants make surgery more aggressive while the third one requires a specific design of the nail. Preference is given to the screw positioned in both cortices tangentially to the nail. It makes the surgery less invasive and provides enough stability if the position of the screw is properly chosen (Figure 9).

Figure 9. Fragment of the CT scan of the femur. The blocking screw inserted correctly.

Biomechanical grounding of this technique is based on that fact that prevention of the transported fragment from axial dislocation is provided by the friction forces between the screw and the nail as well as by the opposite side of the nail that contacts with the bone due to the screw [14]. When the nail is locked, the Ilizarov apparatus can be removed. Wounds are closed in a regular manner. The surgery is finished by applying aseptic dressings.

Postoperative Care after Step 2

On the first postoperative day, aseptic dressings must be changed. X-rays of the limb are taken. Patients can walk with crutches but due to static locking of the nail weight bearing is limited to 20 or 30% of the body mass, especially in obese patients. On the third day, joint motion exercises may be started. Subsequent radiographic examinations are performed in one, three, and six months. In delayed union, dynamisation of the nail is an option of choice. But it is expedient only after the distraction regenerate has fully remodeled to prevent limb shortening.

MATERIALS AND METHODS

Between 2011 and 2014, this technique was used for management of nonunions accompanied by anatomical shortening of the femur in nine patients (two females, seven males, mean age 32.75 years). In all the cases, the initial injuries were closed fractures of the femoral shaft managed with the following techniques: plating in one case (11%), interlocking nailing in four cases (44.5%), and non-interlocking nailing in four cases (44.5%). Nonunions in two patients (one after non-locking and one after interlocking nails) had been treated by reamed interlocking nailing prior to our operation, but union of the femur was not achieved. The mean time passed from the initial injury till our combined fixation was 2 years and 9 months.

Before treatment, all the patients (100%) walked with crutches and experienced pain in the femur after physical activity. The mean anatomical shortening of the limb was 3.71 ± 0.66 cm. The mean bone loss before treatment was 7.86 ± 1.37 % as compared with the contralateral limb.

Radiographic study before treatment showed hypertrophic nonunions of the femoral shaft. That was reason not to use any bone grafting in the nonunion area. Only reaming during nailing was used. X-rays were taken in the AP and lateral views after the first surgery (step 1), every 10 days during distraction, after the second surgery (step 2), and in the rehabilitation period (one month, three and six months after the Ilizarov fixator removal). CT was performed twice: after the Ilizarov fixator was removed and 6 months later for union verification and assessment of distraction regenerate remodeling.

The technique described above was used in all the patients. Distraction was initiated on the fifth day with the rate 1.5 mm per day in six steps, for creating tension forces at the level of the osteotomy. Once the diastasis between the bone fragments was seen on day 10, distraction was continued with the rate of 1 mm per day in four steps. During the entire period of external fixation, supportive compression at the docking site was produced with 1 or 1.5 mm in one step every 7 or 10 days.

Upon limb length equalization, the Ilizarov apparatus was removed and interlocking screws were inserted (step 2).

External fixation index (defined as the duration of external fixation in days divided by the total amount of lengthening in centimeters) and the average rate of distraction were evaluated. All the patients were available for follow-ups (6-12 months) after the external fixator had been removed.

Figure 10. X-ray of the femur in anteroposterior and lateral views. 20 days of distraction. Distraction regenerate with inhomogeneous structure.

RESULTS

On day 10 of distraction, the radiographic examination showed the diastasis that measured 10 ± 1.5 mm in eight cases. In one case, distraction with an advanced rate (1.5 mm per day) continued for five days, and the same radiographic diastasis was achieved.

Regenerate formation was visible by day 20 of distraction. The regenerate had inhomogeneous structure, presented both by periosteal and endosteal reactions (Figure 10). CT scans after step 2 showed that the regenerated bone was continuous, had a cylindrical shape, and zonal structure. Mean bone density was 50.5 ± 16.3 HU (Figure 11).

Mean rate of distraction was 1.25 mm per day. External fixation index was 10.2 ± 0.78 days/cm. Such a short duration of the external fixation can be explained by the fact that the Ilizarov apparatus was used only during distraction. Fixation after lengthening continued with the nail.

Figure 11. Fragments of the CT scan of the femur. Continuous distraction regenerate after step 2.

Figure 12. X-ray of the femur in anteroposterior and lateral view. Outcome in 5 months.

Inflammatory skin problems round two wires were observed in one case during distraction. Those wires were removed and new wires were inserted. Deep infection did not develop. Combined Ilizarov external fixation and nailing allowed us to achieve restoration of the limb length in all the cases. Consolidation of the distraction regenerate was achieved within five to 6 months after the Ilizarov apparatus had been removed. Nonunion healed after five or 6 months in eight cases. On the X-rays, continuity of three or four cortices at the nonunion level and along the regenerate area was seen (Figure 12). CT scans performed at that period showed the density values of 810-950 HU on both levels. In one case, a delayed union was diagnosed at a 6-months' follow-up. Distal interlocking screws were removed in this case, and three months later the bone united. Instability of the nail did not develop. Once the nonunion had healed, all the patients could walk without crutches bearing full weight on the limb.

DISCUSSION

Ilizarov's contribution [4] into the management of bone nonunions and defects is considered to be one of the most important developments in the orthopedics of the XX century [3]. Distraction osteogenesis is still the main method in the treatment of the patients with large bone defects and deformities [9]. Orthopedic problems that cannot be corrected simultaneously have a chance to be eliminated by gradual distraction. However, a long postoperative period with the external fixator on the limb forced the surgeons to search for the ways to shorten that period and improve patients' quality of life. Interlocking nailing was first described by G. Kuentscher. It has evolved to a method with biological justification and worldwide practice in fracture treatment [12]. Reaming of the medullary canal has several biologic effects. One of them is a strong hyperaemic reaction which results in revascularization of the bone cortex [13]. As the area of pseudoarthrosis has a poor blood supply, this effect serves to success in nonunion treatment with nailing [7]. Analyzing all the pros and cons of external fixation and intramedullary nailing, we combined these techniques. Our experimental study has shown that the process of distraction regeneration features the typical pattern, even in the conditions of impaired blood supply. Revascularization after reaming and nail insertion results in an expressed periosteal reaction, both in the nonunion and distraction regenerate areas. Such a periosteal reaction is a sign of adequate blood supply from the periosteum and surrounding soft tissues. It is not caused by instability between bone fragments. In clinical settings, such an approach to nonunion treatment provided the conditions for early rehabilitation and allowed the patients to fulfill more physical activities. Moreover, external fixation period reduced, in-patient stay decreased, and postoperative recovery was faster as compared with the traditional Ilizarov method [10].

CONCLUSION

Intramedullary nailing can be used in combination with the Ilizarov external fixation for management of nonunions accompanied by limb shortening. The combined use of these two techniques allows stimulation of bone formation in the conditions of impaired blood supply. Intramedullary nailing improves the stability of the transported bone fragment and provides an opportunity to remove the Ilizarov apparatus earlier. We conclude that the combined Ilizarov external fixation and nailing is a highly efficient technique to obtain good outcomes in the management of this pathology.

Chapter 9

COMPLICATIONS OF BARIATRIC SURGERY, IMPROVEMENT OF COMORBIDITIES AND IMPACT ON QUALITY OF LIFE

Jaime Ruiz-Tovar^{1,*}, MD, PhD and Carolina Llaveró^{2,†}

¹Department of Surgery. General University Hospital Elche, Spain

²Department of Surgical Nursery. Sureste Hospital, Madrid, Spain

ABSTRACT

More than 2/3 of the U.S. population is overweight or obese. Obesity is on the rise and the incidence is increasing most rapidly in the morbidly obese population, i.e., those with a BMIs exceeding 40 kg/m². Epidemiological studies estimate the prevalence of morbid obesity around 0.5%, but this rate is probably underestimated, as many morbidly obese subjects are not under any medical control. Only surgery results in substantial, long-term weight loss for obese individuals. Therefore, the performance of bariatric procedure has increased exponentially in the last 2 decades; from less than 9,000 procedures in 1993 to a high of over 115,000 in 2004. Actually, the number of bariatric procedures performed is even higher.

Despite nowadays most bariatric techniques are performed laparoscopically, the complications rate still represents a challenge for many surgeons. Complications associated to these approaches are often life-threatening conditions. Morbidly obese patients are high risk subjects and therefore, bariatric surgery must be considered a high risk procedure though the patients are operated for a benign condition. Complications include medical (deep vein thrombosis, pulmonary embolism, atelectasia, pneumonia,...) and surgical items (anastomotic leak, bleeding, surgical site infection,...).

Even considering the surgical risk, bariatric surgery has demonstrated much more advantages than disadvantages. Bariatric surgery can solve many comorbidities, such as diabetes mellitus, hypertension, dyslipidemia, pulmonary disorders, osteoarthritis,..., and reduces significantly the risk of developing new health problems, such as cardiovascular or neoplastic events. Altogether, this leads to a significant improvement of the quality of life. The patients feel healthier and this has a positive psychological impact. There are many scales available to evaluate quality of life, but all of them coincide in that bariatric

surgery achieves a significant improvement in the quality of life of morbidly obese patients.

INTRODUCTION

More than 2/3 of the U.S. population is overweight or obese. Obesity is on the rise and the incidence is increasing most rapidly in the morbidly obese population, i.e., those with BMIs exceeding 40 kg/m². Epidemiological studies estimate the prevalence of morbid obesity around 0.5%, but this rate is probably underestimated, as many morbidly obese subjects are not under any medical control. Only surgery results in substantial, long-term weight loss for obese individuals. Therefore, the performance of bariatric procedure has increased exponentially in the last 2 decades; from less than 9,000 procedures in 1993 to a high of over 115,000 in 2004. It is estimated that 220,000 weight-loss surgeries were performed in 2008. Actually, the number of bariatric procedures performed is even higher. [1]

COMPLICATIONS OF BARIATRIC SURGERY

Complications following surgical treatment of severe obesity vary based upon the procedure performed and can be as high as 40%. Due to the high surgical volume, improving the safety of these operations has become a high priority, leading to the development of strict criteria for center accreditation, guidelines for safe and effective bariatric surgery, and careful monitoring of surgical outcomes. [1,2] Operating on obese patients is challenging because of anatomic and physiologic characteristics and comorbidities of obese patients. However, the risk of serious intra-operative and in-hospital complications and mortality rates are relatively low when the surgery is performed by experienced surgeons with an institutional investment in bariatric programs.

Postoperative complication rates vary with surgical approach, such as fewer complications with the laparoscopic approach than the open approach. Complications also vary based upon type of procedure, such as fewer complications with the adjustable gastric band (AGB) than the laparoscopic Roux-en-Y gastric bypass (LRYGB). [1-3]

ADVERSE INTRA-OPERATIVE EVENTS (AIE)

The adverse intra-operative event (AIE) rate varies with the complexity of the procedure, ranging in contemporary reports from <1% to 5%. [3] The most common AIE in laparoscopic surgery include:

- Anesthesia events (1%)
- Instrument/equipment failure (0.8 %)
- Bowel injury (0.8 %)
- Hepatic injury (0.4 %)
- Anastomosis revision (0.3 %)

- Splenic injury (0.2 %)
- Major blood vessel injury (0.1 %)

In addition, previous intra-abdominal operations can create extensive adhesions, and abdominal wall procedures (i.e., abdominoplasty) can restrict insufflation and reduce the visible surgical field.

Trocar placement, blind insertion of the laparoscopic instruments, thermal injury or excess traction/manipulation of organs can contribute to some of the more common intra-operative laparoscopic complications.

Trocar Related Injuries

Peritoneal access by precise placement of the trocar and Veress needle is technically challenging in the patient with a thick abdominal wall; however, all types of entry access (e.g., open, closed, or optical view) can be safely performed by experienced surgeons. There is no statistical difference in the rates of major complications (e.g., vascular or solid organ injury) for open, closed, or optical view laparoscopic entry techniques. [4]

Spleen Injury

The spleen can be injured during weight-loss surgery, especially during a Laparoscopic sleeve gastrectomy (LSG), but bleeding can usually be controlled with hemostatic agents, and splenectomy is rarely required. [5]

Portal Vein, Inferior Vena Cava Injuries

Intra-operative injury to the portal vein and inferior vena cava is rare during bariatric operations, but can lead to rapid exsanguination. If thrombosis of the portal vein occurs following an injury, these patients require liver transplantation. [6]

Bowel Ischemia

During the performance of RYGB or BPD-DS procedures in particular, ischemia of the bowel may result if the root of the mesentery containing the mesenteric vessels is compromised or undermined during transection of the small bowel. [7]

Bowel ischemia may occur during bariatric operations in the following cases:

- Twisting the mesentery and/or mesenteric root while performing a retrocolic anastomosis for a RYGB
- Creating tension on the Roux-en-Y limb when performing a gastrojejunal anastomosis

- Incising the mesentery of the biliopancreatic limb or Roux limb at an angle such that blood flow to an end of intestinal limb is compromised.
- Closing the mesenteric defect with overly generous amounts of tissue between sutures
- Internal hernias at Petersen's defect (between the Roux limb mesentery and the transverse colon mesentery), through the transverse mesocolon itself in a retrocolic anastomosis, or the jejunojejunostomy site can also lead to ischemia and, therefore, these defects must be closed. An antecolic limb does not rule out the possibility of a future internal hernia through this potential space, but this is not likely to occur early after a RYGB.

Solid Viscus Organs

The liver can be injured during bariatric surgical procedures because of its close proximity to the stomach, especially during vertical sleeve gastrectomy. Bleeding can usually be controlled with hemostatic agents and a partial hepatectomy is rarely required. [4]

Hollow Viscus Organs

Bowel injury, such as a puncture or laceration, can occur with insertion of a Veress needle, trocar, lysis of adhesions, or dissection. [4]

Misconstruction

Misconstruction of a Roux-en-Y bypass or a biliopancreatic diversion–duodenal switch (BPD-DS) can occur during a laparoscopic or open approach. Proper bowel orientation must be maintained to avoid misconstruction. Misconstructions of the Roux-en-Y bypass with an anastomosis between the distal aspect of the biliopancreatic limb and the gastric pouch have been reported and lead to chronic bilious vomiting ("Roux-en-O"). Other examples of misconstruction include Roux limb inversion and short Roux limb. [8]

IN-HOSPITAL POSTOPERATIVE MORBIDITY

The risk of a major complication immediately after the operation ranges from approximately 0.2% to 10% in contemporary series, depending upon patient comorbid illnesses, type of procedure, surgical approach (laparoscopic or open), and surgeon expertise.

Anastomotic Leak

The anastomotic leak remains the most dreaded technical complication of bariatric surgery and is one of the most challenging complications of weight-loss surgery. The risk of a

leak ranges from 0.8% to 6%. The risk approaches 35% in revisional bariatric surgery. Most leaks occur early, generally within the first week after surgery but can occur up to a month after the operation. [9-11]

The clinical presentation is subtle and requires vigilance for signs such as low-grade fevers, respiratory compromise, and/or unexplained tachycardia greater than 120 bpm. These signs may also be present in the setting of pulmonary embolism. A leak may be radiographically confirmed by barium swallow or contrast computed tomography (CT). If a leak is suspected clinically, emergent surgical exploration should be performed, even if the imaging is negative, given the rapid progression to sepsis in the severely obese patient with comorbidities. A negative exploration that does not reveal a leak should not be considered a complication but rather evidence of good surgical judgment. Multiple studies have shown that re-exploration is safe when compared with missing or delaying the treatment of a leak. In experienced hands, surgical exploration and management of a leak is often feasible via a laparoscopic approach.

The surgical principles in treating a leak include:

- Broad-spectrum antibiotic coverage
- Identification and repair of the defect
- Irrigation and control of contamination
- Wide external drainage of the contaminated area
- Enteral access for feeding, most commonly a gastric feeding tube placed in the gastric remnant

Percutaneous drainage of a contained fluid collection may be an option in patients who are stable. Surgical therapies for persistent gastric leak are technically difficult and often unsuccessful. New approaches using minimally invasive endoscopic repair techniques appear safe and effective in some patients. These include use of glue, or placement of covered stents across the leak. Many different intraoperative techniques have been used to decrease the incidence of leaks. Over-sewing staple lines, buttressing materials for the staple line and fibrin glue have been used, but there is no evidence that these methods reliably decrease the leak rate after bypass surgery. [12,13]

Hemorrhage

Significant bleeding after gastric bypass has been described in 0.4% to 4% of patients. Bleeding can occur from the gastric or short gastric vessels during dissection of the greater curve. Most of the bleeding problems associated with a sleeve gastrectomy occur from the staple line after transection of the stomach. The bleeding is most likely a result of the large staples used for the thick tissue in the distal stomach. Large staples are not adequate to seal small vessels. This has led many surgeons to reinforce the staple line by over-sewing, buttressing, or both. [14]

Early bleeding typically can also occur from an anastomosis; more commonly, intraluminal bleeding occurs. Patients frequently present with tachycardia, a decreased hematocrit, and melena. Such bleeding typically resolves without surgical intervention, but may require transfusion of blood products and reversal of anticoagulation. Careful endoscopic

examination and therapy is appropriate for ongoing bleeding with high transfusion requirements. Surgery is reserved for hemodynamic instability, intraluminal bleeding not amenable to endoscopic therapy (e.g., staple line of the excluded stomach), or continued bleeding despite restoration of normal coagulation status. [15,16]

Venous Thromboembolism/Pulmonary Embolism

The overall incidence of a venous thromboembolism (VTE)/pulmonary embolism (PE) is approximately 0.4%. The incidence is around 0.3% for laparoscopic procedures and 1.2% for open procedures.

The most common risk factors associated with fatal PE include severe venous stasis disease, BMI >60, truncal obesity, and obesity-hypoventilation syndrome. [17]

Optimal strategies for preventing VTE/PE in the bariatric surgery setting have not been established. Most bariatric surgeons use both pneumatic compression devices in conjunction with subcutaneous unfractionated or low molecular weight heparin. The current American Society of Bariatric and Metabolic Surgeons (ASMBS) guidelines regarding VTE prophylaxis state that all bariatric patients receive mechanical prophylaxis and are ordered for early ambulation. Additionally, the surgeon may routinely use chemical prophylaxis of either low molecular weight heparin or unfractionated heparin. [18]

Preoperative risk stratification may be a useful tool for identifying high-risk patients for more aggressive prophylaxis. In patients identified preoperatively as high risk for PE, due to previous medical history of VTE, PE, or venous stasis disease, or inability to ambulate (i.e., wheelchair-bound), perioperative chemoprophylaxis of low molecular weight heparin or unfractionated heparin may be prescribed for an extended period even after discharge from the hospital. [19]

Myocardial Infarction

The incidence of a postoperative MI after a bariatric operation is approximately 0.2%. [1]

Pulmonary Complications

Major postoperative pulmonary complications include pneumonia and acute respiratory failure. Atelectasis is common after all types of surgery that require general anesthesia, and is more prevalent in the morbidly obese. The overall incidence of postoperative pneumonia is around 0.4%. The overall rate of acute respiratory failure (ARF) is 1.3%. The incidence is higher with an open compared with a laparoscopic procedure, gastric bypass procedures compared with restrictive procedures and for patients with preoperative heart failure, chronic renal failure, peripheral vascular disease, chronic obstructive pulmonary disease (COPD), tobacco smoking, and diabetes. ARF is associated with a significantly higher in-hospital mortality rate compared with those who do not develop the complication.

Early ambulation and incentive spirometry after surgery are important to decrease the incidence of pulmonary complications. Preoperative identification of the presence of

significant obstructive sleep apnea and initiation of continuous positive airway pressure (CPAP) therapy also reduce the risk of pulmonary complications in the postoperative period. CPAP should be used in the early postoperative period if it is clinically necessary. [20]

Surgical Site Infections

Surgical site infections (SSIs), which often are localized to the incision but can extend into deeper tissues, are the most common nosocomial infection, and are found in 2% to 5% of surgical operations in the United States. SSIs are associated with substantial morbidity, mortality, prolonged hospital stay, and increased cost of care. An overall incidence of SSIs of 1.1% has been described for bariatric surgery. Rates of wound infection are significantly greater for open procedures (10 – 15%) compared with laparoscopic (3 - 4%) procedures. Among laparoscopic techniques, rates of wound infection vary depending upon the technique used, with a higher rate of wound infections associated with the use of circular stapling devices to create the gastrojejunostomy. [21]

Signs of wound infections include unexplained fever, fluctuance, erythema, or drainage. Treatment consists of opening the affected area for drainage of infected fluid or pus, debridement of any devitalized tissue, and antibiotics if the surrounding skin suggests signs of cellulitis. The incidence of SSIs can be decreased by perioperative administration of antibiotics. [22]

In-Hospital Mortality

The intra-operative mortality is dependent upon multiple factors, including the technical difficulty of selected procedure (for example, BPD-DS technically more difficult than LAGB), patient selection (e.g., body habitus), presence of comorbid illnesses (e.g., COPD, congestive heart failure), skill of the surgeon (learning versus expert), institutional resources, and volume of procedures performed. While there are limited data available, the overall intra-operative mortality rates that are reported as well as the overall in-hospital mortality rates are typically <1% in most contemporary series. [23]

Pulmonary embolism (PE) remains the most common cause of mortality in the perioperative period after bariatric surgery, and accounts for approximately 30 – 50% of deaths. The mortality rate of a pulmonary embolism is dependent upon the severity of presentation and time to diagnosis/treatment, and widely varies from 1% to 95%. The majority of deaths occur within the first one to two hours after the embolism. [24]

Other common, serious causes of in-hospital mortality include cardiac events (12-17%), respiratory failure (11%), and septic complications related to an anastomotic leak (15%). [24]

30 DAYS MORBIDITY AND MORTALITY

Early morbidity and mortality rates that occur ≤ 30 days after the operation are generally low and vary with surgical approach, such as fewer complications and less mortality with the

laparoscopic than the open approach. Most patients have been discharged from the hospital during this one-month interval after the operation. Serious complications that occur during the in-hospital admission can also occur after discharge, such as a pulmonary embolus or myocardial infarction. The overall morbidity rate for serious complications ranges from approximately 3.4% to 12%, and varies with operative procedure (e.g., RYGB, LAGB), operative approach (open versus laparoscopic), patient age, body mass index (BMI), and comorbid illnesses. The morbidity associated with LAGB appears to be less than is seen with laparoscopic Roux-en-Y gastric bypass (LRYGB). The biliopancreatic diversion with duodenal switch (BPD-DS) appears to be the riskiest procedure with the highest 30-day mortality of 1.2%, and the one associated with the most complications and highest morbidity rates. [25-26]

Marginal Ulcers

Marginal ulcers typically occur within 30 days after the RYGB operations at the gastrojejunal anastomosis and at the gastroileal junction following a BPD-DS, despite bypass or removal of most of the acid secreting cells of the stomach. The risk of a marginal ulcer following bariatric operations varies between 1.2% and 12%. The clinical presentation of marginal ulcers includes melena, hematochezia, hematemesis, or pain and obstructive symptoms as the swollen mucosa can occlude the anastomosis to the small intestine. Early ulceration most likely is related to ischemia, too large of a pouch, or undiagnosed *Helicobacter pylori* (*H. pylori*) infection. [27]

Risk factors for late presentation of a marginal ulcer include smoking, nonsteroidal antiinflammatory drugs (NSAID), or gastrogastic fistula formation. Lifetime avoidance of smoking and NSAIDS is advised. If NSAIDS are necessary, a concomitant use of a proton pump inhibitor is advised. [28]

Stenosis

Stenosis occurs when the gastrojejunal anastomosis of a RYGB or gastroileal anastomosis of a BPD-DS becomes occluded secondary to tissue edema or a narrow anastomosis. Following a LSG, stenosis can occur if the sleeve narrows, kinks, or twists. A retrospective review of 230 patients found that the risk of stenosis following a LRYGB, BPD-DS, or LSG is approximately 3.3%, 1.2%, and 3.5%, respectively. [29]

The clinical presentation is consistent with an obstruction and includes nausea, vomiting, abdominal pain, and dysphagia. Endoscopic balloon dilation of the stenotic structure is the first management option.

Stomal Obstruction

Acute stomal obstruction is an early complication that can occur in up to 14% of LAGB patients. Obstruction is usually caused by inclusion of excess perigastric fat, use of a band of insufficient diameter for the thickness of the tissue, or significant tissue edema. Patients

usually present with persistent nausea, vomiting, and inability to tolerate secretions or oral intake. The diagnosis is confirmed with an upper gastrointestinal series demonstrating no passage of contrast beyond the band.

Acute stomal obstruction due to edema can initially be treated conservatively with nasogastric tube decompression until the edema subsides, although a potential for aspiration pneumonia and gastric ischemia exists. Persistent obstruction requires surgical revision or removal of the band. Meticulous removal of excess perigastric fat at the time of initial band placement may help prevent this complication. The use of larger diameter bands may also help to reduce the incidence of acute postoperative obstruction. [30]

30 Days Mortality

The overall 30-day postoperative mortality rate is generally less than 1% in most contemporary series. Mortality rates are higher for patients undergoing more complex operative procedures, or who sustain adverse intra-operative events or serious in-hospital complications (such as PE or acute respiratory failure [ARF]) as well as those with a BMI ≥ 50 kg/m², older age, and medical comorbidities. The mortality rate was greater for patients undergoing an open procedure compared with a laparoscopic procedure (0.79% versus 0.17%). The most common causes of death varied with the series but generally include pulmonary embolism, sepsis, complications of anastomotic leak, cardiac events, and small bowel obstruction.

Specific risk factors for mortality are male gender, older age (>65 years), excessive obesity (BMI ≥ 50 kg/m²), comorbid illnesses, poor functional status, low-volume surgeons and hospitals (<100 procedures/year). [31,32]

LATE COMPLICATIONS

Complications of bariatric surgery that occur after 30 days include cholelithiasis, nutritional deficiencies, and neurologic and psychiatric complications.

Cholelithiasis

Cholelithiasis develops in as many as 38% of patients within six months of surgery, and up to 41% of such patients become symptomatic. Rapid weight loss can also contribute to the development of gallstones by increasing the lithogenicity of bile. The high frequency of cholelithiasis can be reduced to as low as 2% percent with a six month course of ursodeoxycholic acid given prophylactically after weight-loss surgery. The decision to perform a cholecystectomy at the time of bariatric surgery is controversial. Some surgeons recommend performing cholecystectomy at the same time if a patient has symptomatic gallstones preoperatively. The surgical opinion about asymptomatic gallstones is more divided, and studies have failed to demonstrate a benefit for simultaneous cholecystectomy for incidental gallstones.

Patients can also develop choledocholithiasis, which can be difficult to treat in the postoperative course of RYGB. Diagnosis of choledocholithiasis can be confirmed by ultrasound or magnetic resonance cholangiopancreatography (MRCP); however, endoscopic intervention and management can be difficult because of the relative inaccessibility to the duodenum due to the altered anatomy of the Roux-en-Y configuration. As a result, successful endoscopic retrograde cholangiopancreatography (ERCP) with cannulation of the papilla is very difficult to perform. Thus, treatment of choledocholithiasis may require surgery or transhepatic percutaneous access. [33,34]

Ventral Incisional Hernia

Ventral incisional hernias occur with a frequency of 0 - 1.8% in laparoscopic series and as high as 24% in open series, underscoring a clear advantage of the laparoscopic approach in this regard. Incisional hernias present with an enlarging bulge, pain, or obstructive symptoms. Severe obesity is associated with increased intra-abdominal pressure and thus, a high risk of hernia development after a laparotomy. Many surgeons postpone a formal repair until significant weight loss occurs (>1 year). Indications for early surgical repair include significant pain, bowel obstruction, and rapid enlargement of the hernia. [35]

COMPLICATIONS OF SPECIFIC BARIATRIC PROCEDURES

Roux-En-Y Gastric Bypass

Gastric Remnant Distension

Gastric remnant distension is a rare but potentially lethal complication following gastric bypass. The gastric remnant is a blind pouch and may become distended if paralytic ileus or distal mechanical obstruction occurs postoperatively. Iatrogenic injury to vagal fibers along the lesser curvature may also contribute, possibly by leading to impaired emptying of the bypassed stomach. Progressive distension can ultimately lead to rupture, spillage of massive gastric contents, and subsequent severe peritonitis. The combination of the large size of inoculum (liters) and the injurious contents (acid, bile, pancreatic enzymes, and bacteria) makes this complication much more serious than leakage occurring at the gastrojejunostomy.

Clinical features include pain, hiccups, left upper quadrant tympany, shoulder pain, abdominal distension, tachycardia, or shortness of breath. Radiographic assessment may demonstrate a large gastric air bubble.

Treatment consists of emergent operative decompression with a gastrostomy tube or percutaneous gastrostomy. Immediate operative exploration and decompression are required if percutaneous drainage is not feasible, or if perforation is suspected. Although gastrostomy is not performed routinely by most surgeons at the initial gastric bypass operation, drainage of the gastric remnant can prevent this rare but sometimes fatal complication. Routine gastrostomy should be considered in the elderly, super-obese patients, patients with diabetic gastropathy and as part of revisional surgeries where gastric emptying may be delayed. [36]

Dumping Syndrome

Dumping syndrome can occur in up to 50% of postgastric bypass patients when high levels of simple carbohydrates are ingested. Dumping may contribute to weight loss in part by causing the patient to modify the eating habits.

There are two types of dumping syndrome: early and late. [37]

- Early dumping syndrome — Early dumping syndrome has a rapid onset, usually within 15 minutes. It is the result of rapid emptying of food into the small bowel. Due to the hyperosmolality of the food, rapid fluid shifts from the plasma into the bowel occur, resulting in hypotension and a sympathetic nervous system response. Patients often present with colicky abdominal pain, diarrhea, nausea, and tachycardia. Patients should avoid foods that are high in simple sugar content and replace them with a diet consisting of high fiber, complex carbohydrate, and protein rich foods. Behavioral modification, such as small, frequent meals, and separating solids from liquid intake by 30 minutes, are also advocated. Usually, early dumping is self-limiting and resolves within 7 to 12 weeks.
- Late dumping syndrome — Late dumping syndrome is a result of the hyperglycemia and the subsequent insulin response leading to hypoglycemia that occurs 2 to 3 hours after a meal. Patients present with dizziness, fatigue, diaphoresis and weakness. The treatment is similar to early dumping syndrome.

Metabolic and Nutritional Derangements

Metabolic and nutritional derangements are common in severely obese patients and can be exacerbated following after bariatric surgery, making postoperative life-long compliance with appropriate dietary choices and vitamin supplementation imperative. Decreased oral intake as well as altered absorption of food from the stomach and small bowel reduces absorption of various micronutrients, particularly iron, calcium, vitamin B12, thiamine and folate. Hyperoxaluria and nephrolithiasis have been reported following Roux-en-Y gastric bypass surgery.

Change in Bowel Habits

Loss stool and diarrhea are more common after BPD and RYGB. Constipation is more common after gastric banding. Steatorrhea and more frequent stools can occur with excessive fat intake. In addition, these symptoms can be due to subclinical lactose intolerance, which is only recognized when dairy products are used in an effort to achieve adequate protein intake after bariatric surgery. [38]

Failure to Lose Weight and Weight Regain

Failure to lose weight following Roux-en-Y gastric bypass is rare, and is often due to maladaptive eating patterns during the early postoperative period. On the other hand, significant late weight regain occurs in up to 20% of patients, especially those with super-obesity (BMI >50 kg/m²) at the time of the initial operation. It is often due to progressive noncompliant eating and other behavioral habits, development of a functional gastrogastic fistula, gradual enlargement of the gastric pouch, or dilatation of the gastrojejunal anastomosis. [39]

Gastric Banding

Band Erosion

Band erosion through the wall of the stomach has been reported in up to 7% of GB patients, and it is thought to occur as a result of either gastric wall ischemia from an excessively tight band, mechanical trauma related to the band buckle or thermal trauma from electrosurgical energy sources used during band placement. Band erosion is a late complication and occurs at a mean of 22 months after surgery.

Clinical signs of band erosion include infection, failure of weight loss, or nausea and vomiting. Epigastric pain and hematemesis can also signal erosion of the lap band into the left gastric artery. This can happen when the lap band erodes into the posterior part of the stomach near the cardioesophageal junction. This complication can be avoided by careful placement during the initial surgery, making sure not to include the ascending branch of the left gastric artery during band placement.

Band erosion can be diagnosed by endoscopy and treatment involves removal of the band, which can be done laparoscopically. It is generally recommended that revision to another bariatric procedure be delayed for at least 2 to 3 months after an episode of band erosion, as the complication rate with immediate revision is increased. [40]

Band Slippage and Gastric Prolapse

Band slippage involves prolapse of part of the stomach through the band, with varying degrees of gastric obstruction. Slippage rates can be as high as 24%.

- Anterior prolapse involves migration of the band cephalad which creates an acute angle with the stomach pouch and esophagus, resulting in obstruction.
- Posterior gastric prolapse occurs when the stomach migrates cephalad, displacing the band caudally and creating a new pouch

Gastric prolapse is characterized by food intolerance, epigastric pain, and acid reflux. Diagnosis is confirmed with an upper gastrointestinal series demonstrating either malposition of the band or dilatation and prolapse of the gastric pouch.

Surgery is required urgently or emergently, depending on the presentation. Repair of the prolapse can sometimes be accomplished by repositioning the band, but often the band needs to be replaced or removed altogether, especially if significant inflammation is found. [41]

Port Malfunction

Port malfunction results if the tubing disconnects, subcutaneous port flips, or leakage within the system occurs. Such problems lead to inability to titrate the instilled volume of saline in the system. Reported incidence of port and tubing malfunction ranges from 0.4% to 7%. These problems usually become evident as an inability to access port and maintain band volume, or the development of weight gain. These complications require surgical repair or exchange of the hardware to attain band adjustability. Port dislocation can be reduced by attaching the port to a broad surface mesh first before anchoring to the rectus fascia. [42]

Esophagitis

Esophagitis and reflux are infrequent complications following Lap-Band. Deflation of the band and acid-suppression therapy are the mainstays of treatment. However, if intractable to medical therapy, band removal or conversion to other procedure such as RYGB may be necessary. [43]

Esophageal Dilatation

Esophageal dilatation proximal to the band device has been observed in as many as 10% of patients. This so-called "pseudoachalasia syndrome" may develop when the band is excessively inflated or in the setting of excessive amounts of food intake. Pouch dilatation has also been associated with a history of binge eating behavior. Patients often present with food and saliva intolerance, reflux and epigastric discomfort. The diagnosis can be confirmed with an upper gastrointestinal series.

The initial treatment should be removal of all the fluid from the band and behavioral diet modifications. This is usually successful in reversing esophageal dilatation. However, persistent dilatation may require replacement of the band in a new location on the stomach or conversion to a different procedure.

Deflation of the band alone is usually successful in reversing esophageal dilatation. However, persistent dilatation may require replacement of the band to a new location on the stomach or conversion to a different procedure. [44]

Hiatus Hernia

Hiatus hernia is often a pre-existing but unrecognized condition in patients undergoing bariatric surgery. This can lead to ongoing intractable reflux necessitating reoperation or band removal. Thus, a simple crural repair can be performed at the initial operation to avoid these complications. [45]

Sleeve Gastrectomy

Bleeding

Bleeding can occur from the gastric or short gastric vessels during dissection of the greater curve. Most of the bleeding problems associated with SG occur from the staple line after transection of the stomach. The bleeding is most likely a result of the large staples used for the thick tissue in the distal stomach. Large staples are not adequate to seal small vessels. This has led many surgeons to reinforce the staple line by over-sewing, buttressing or both. [46]

Stenosis

Narrowing or stenosis can create gastric outlet obstruction. The presentation varies depending on the severity of the obstruction and can include dysphagia, vomiting, dehydration and the inability to tolerate an oral diet.

The gastroesophageal junction and the incisura angularis are the two most common areas where stenosis occurs, and this can be diagnosed by an upper gastrointestinal series.

The most common reasons for the development of narrowing or stenosis are over-sewing the staple line and using a bougie that is too small. The preferable bougie size is currently debated in the literature and can range from 30 to 60 French. In most cases, surgeons use a 36 to 40 French bougie for the sleeve construction and the larger sizes of bougies are reserved for when SG is being performed as part of a staged procedure.

Management of stenosis primarily consists of endoscopic dilation. If the area of stenosis is too long, surgical intervention may be necessary with conversion to a RYGB, gastric stricturoplasty or resection with gastrogastrostomy. [47]

Gastric Leaks

Gastric leaks after SG are one of the most serious complications and can occur in up to 5.3% of patients.

Most leaks are due to local factors at the site of the staple line, such as inadequate blood supply and oxygenation, which impede the healing process. Leaks can also be due to gastric-wall heat ischemia, a consequence of the heat generated by the cautery used during dissection of the greater curve. Although the blood supply to the stomach is robust, the gastroesophageal junction tends to be an area of decreased vascularity and thus more prone to leaks. Additionally, the stomach tends to be thinner at the angle of His and some authors suggest that the large staple height used by many surgeons may not adequately seal this area of the stomach.

Some surgeons recommend leaving a small portion of stomach distal to the angle of His and then imbricating with a running suture. However, clinical studies have not provided evidence that reinforcing the suture line decreases the rate of leak after sleeve gastrectomy. Sleeve gastrectomy produces high intragastric pressure, which can affect the healing process and lengthen the amount of time for a leak to close. [48,49]

Reoperation with primary repair during the early postoperative course is the best option for a leak following SG. Clinically stable patients may be able to undergo percutaneous drainage, antibiotic therapy, and parenteral nutrition until the leak is healed. Endoscopic therapy with the use of stents has also been employed for management of leaks, but migration of the stents has been a problem. Early diagnosis, adequate drainage and gastric decompression are the mainstay of treatment for leaks. [50]

Reflux

Gastroesophageal reflux after SG presents with classic symptoms such as burning pain, heartburn, and regurgitation. It can occur as an early and late complication. The first-line treatment is antireflux medical therapy. GERD unresponsive to antireflux medical therapy with no clear anatomic abnormalities, such as stoma stenosis or a hiatal hernia, can be effectively treated by conversion to RYGB. [51]

Pure Malabsorptive Procedures (Biliopancreatic Diversion and Duodenal Switch)

Electrolyte Imbalances

Over half of the patients who underwent, malabsorptive procedures developed diarrhea and electrolyte imbalances, and these problems could persist more than five years after

surgery. Arthritis, protein malnutrition, vitamin deficiencies, cirrhosis, nephrolithiasis with oxalate stones and renal failure have also been associated. [52]

Renal Failure

Increased absorption of calcium oxalate leads to deposition in the renal parenchyma. This can lead to a postobstruction nephropathy and renal failure, which has been described in up to 20% of patients. Conversion to a gastric bypass or reversal should be considered in patients with metabolic complications. [53]

Cirrhosis

Hepatic abnormalities that may lead to cirrhosis can occur in up to 40% of patients and may persist or progress despite reversal in more than one-third of patients. Some patients have progressed to decompensated cirrhosis requiring transplantation. Progressive liver injury appears histologically as increasing steatosis, lobular lymphocytic inflammation, pericellular fibrosis, Mallory bodies, and deranged architecture, all features resembling those seen in alcoholic liver disease. [54]

IMPROVEMENT OF COMORBIDITIES

Weight Loss

Excess Body Weight

Excess body weight is defined as the amount of weight that is in excess of the ideal body weight. Ideal body weight is conventionally determined by the body mass index (BMI) $<25 \text{ kg/m}^2$.

Based upon prospective studies and a randomized trial, the rate of weight loss varies with the specific bariatric procedures, as illustrated:

- For patients undergoing a Roux-en-Y Gastric Bypass (RYGB) or a sleeve gastrectomy (SG), weight loss occurs rapidly over the first few months, then continues over the next year to year and a half until weight loss reaches a plateau. During the first six months after RYGB, the average weight loss is 4.5 to 7 kg per month. Thus, average weight loss at the six-month follow up visit is 27 to 36 kg. Thereafter, the rate of weight loss tends to slow down to 2 to 3 kg per month, and total weight loss reaches a peak at 12 months postoperatively, averaging 45 to 54 kg.
- For patients who undergo an adjustable gastric band (AGB) procedure, weight loss is slower, with an anticipated one pound per week weight loss until stabilization is reached at approximately two years. Although most patients do well initially, some ultimately fail to sustain their improvement. Some AGB patients may not ever achieve significant weight loss. This highlights the importance of establishing a fundamental life-style change during the first one to two years after surgery in order to achieve long-term success in maintaining weight loss. [55-57]

Medical Comorbidities

Diabetes Mellitus

Bariatric surgical procedures are effective interventions for treating type 2 diabetes. Improvement in metabolic control is often evident within days to weeks following bariatric procedures, most likely reflecting an alteration in metabolism that is independent of weight loss. [58]

Three randomized trials illustrate the efficacy of weight loss surgery versus medical therapy alone:

- Obese patients with uncontrolled type II diabetes undergoing a RYGB or a SG plus medical therapy were significantly more likely to achieve the main outcome of a glycated hemoglobin level of 6.0 percent or less at 12 months compared with patients managed by intensive medical therapy alone (42% versus 37% versus 12%, respectively). [59]
- A randomized trial of 60 patients also found that obese diabetic patients undergoing a bariatric operation had better control than medical management alone. Obese patients (BMI ≥ 35) with a history of diabetes for five or more years and a glycated hemoglobin level ≥ 7.0 percent undergoing a RYGB or biliopancreatic diversion (BPD) were significantly more likely to achieve the study endpoint of remission of diabetes at two years compared with patients managed by medical therapy alone (75% versus 95% versus 0%, respectively). [60]
- A randomized trial that included 120 patients demonstrated that a RYGB procedure was superior to intensive medical management alone in achieving the main outcome measure of a glycated hemoglobin level of less than 7%. (75% versus 32%). [61]

Results following RYGB operation are promising and several trials are in progress to evaluate the procedure for patients with BMI < 35 and poorly controlled type 2 diabetes. [62,63] Efficacious control of type 2 diabetes has also been demonstrated following a SG or an AGB.

In 2011, the American College of Surgeons Bariatric Surgery Center Network (ACS-BSCN) found that the remission or improvement was for patients undergoing RYGB, SG, and AGB. In a prospective, longitudinal study that included bariatric-specific data from more than 100 participating institutions and 28,616 obese diabetic patients, remission or improvement in diabetes at 12 months was achieved in 83 percent of patients undergoing a RYGB, 55 percent undergoing SG, and 44 percent undergoing an AGB. [64] This result has been corroborated by other studies demonstrating one-year remission or improvement of diabetes in 40% to 75% of patients who underwent a SG or an AGB. [27,28,65,66]. SG is an alternative procedure to RYGB for patients with BMI < 50 , the extremes of ages, and smokers.

In addition to glycemic control, improvement in distal peripheral neuropathy was identified following RYGB. An improvement or normalization of the Neuropathy Symptom Score (NSS) and the Neuropathy Deficit Score (NDS) in all patients has been found. [67]

Hypertension

The association between obesity and the development of hypertension is well established. Weight loss, whether by an intensive lifestyle-medical modification program or a bariatric operation, improves obesity-linked hypertension or contributes to remission. Patients undergoing a bariatric surgery plus intensive lifestyle medical management were able to achieve a similar reduction in systolic blood pressure at 12 months compared with patients managed with lifestyle medical modification alone. [68] While intensive lifestyle modification resulting in weight loss appears beneficial for resolution of hypertension, this is unfortunately not feasible for all patients, due to reasons such as lack of motivation or inability to exercise.

Data are unclear as to whether or not RYGB offers the highest resolution or reduction of hypertension of bariatric operations, as illustrated by several studies. [64,69]

Dyslipidemia

Obesity-linked dyslipidemia is a well-established risk factor for cardiovascular disease. [70] The most commonly encountered dyslipidemias in obese individuals include hypertriglyceridemia, decreased HDL-cholesterol values, and increased LDL-cholesterol particles. [71] Multiple studies have demonstrated improved lipid profiles following bariatric procedures. The most extensively studied procedure is the RYGB. Mean total cholesterol levels decreased by 16%, triglyceride levels decreased by 63%, LDL-cholesterol levels decreased by 31%, total cholesterol/HDL-cholesterol risk ratio decreased by 60%, and HDL-cholesterol levels increased by 39%. In addition, over 80% of patients requiring lipid-lowering medications preoperatively no longer required medical therapy. [72] Malabsorptive procedures obtain at least similar results of improvement of dyslipidemia. A recent study of our group has demonstrated that after SG, HDL-cholesterol values increase and Triglycerides levels decreased significantly. However, total and LDL-cholesterol remained unaltered of present nonsignificant improvements. Notwithstanding, mainly based on the HDL-cholesterol increase, the cardiovascular risk index present a significant improvement after surgery. [73]

Obstructive Sleep Apnea

An increased prevalence of obstructive sleep apnea in the obese population is well established. [74] Weight loss decreases apnea hypopnea index (AHI, the number of apneas and hypopneas per hour of sleep). In addition, weight loss achieved from bariatric operations also reduces AHI and appears to be similar to the efficacy of behavioral modification weight loss. However, a meta-analysis of 69 studies performed in 2013 identified a high rate of resolution or improvement in OSA following bariatric procedures. [75]

Gastroesophageal Reflux Disease

Obesity is a well-established risk factor for the development of gastroesophageal reflux disease (GERD). The impact of bariatric surgery on development, resolution, or exacerbation of GERD is an evolving topic of debate. Improvement of GERD may be dependent upon the type of bariatric procedure performed. RYGB may improve or ameliorate GERD symptoms. In addition, there is a significant improvement in esophagitis, presence of extraesophageal syndromes, use of proton pump inhibitors, and decreased total acid exposure. [76]

There are conflicting and inconclusive data on the association between AGB and prevalence of postoperative GERD. A systematic review that included 20 studies and 3307 obese patients undergoing AGB found a decrease in prevalence of postoperative GERD compared with the prevalence of preoperative one (7.7% versus 32.9%. In addition, the rate of use of anti-reflux medications decreased in the AGB postoperative period, the prevalence of pathologic reflux also decreased in the postoperative period, and the lower esophageal pressures improved after AGB. However, reflux symptoms developed in the postoperative period in 15% of patients who were asymptomatic preoperatively, and the rate of esophageal dysmotility increased following AGB. Based upon this review, it appears that AGB may have anti-reflux properties for some obese patients, but the procedure may also be associated with the development or worsening of reflux symptoms. [77]

While also highly debated, SG may be the least efficacious procedure to reduce postoperative GERD. In a systematic review of 11 prospective and retrospective studies that included 1058 patients, seven studies identified a decrease in GERD prevalence and four studies found an increase in GERD. [78] This lack of consensus regarding the association between SG and GERD was again reiterated during the 2011 International Sleeve Gastrectomy Expert Panel Consensus Statement where no consensus was reached regarding performance of sleeve gastrectomy in patients with gastric reflux. [79] Based on these data, we consider that preoperative GERD is a relative contraindication for undergoing a SG and in such cases we prefer performing a RYGB. [73]

Polycystic Ovary Syndrome

Polycystic ovarian syndrome (PCOS) is found in 30% to 70% of obese women of reproductive age and is associated with a high risk of infertility. [80] Weight reduction through diet and exercise and lifestyle modification can improve the hyperandrogenemic symptoms and insulin resistance associated with PCOS. Bariatric surgery is an alternative strategy for weight loss in women with PCOS. Obese women who effectively achieved weight loss following a RYGB had restored menstrual cycles at approximately three to four months following the operation, marked lessening of hirsutism and hyperandrogenemia at eight months, and an increased ability to conceive within two years of surgery. Similar studies have not been published for adjustable gastric band or sleeve gastrectomy. [81,82]

Oncologic

The association between obesity and certain cancers, such as breast, endometrial, colon, renal, and pancreatic cancers has been well established. Obesity also increases the likelihood of worse oncologic outcomes. The impact of bariatric surgery on oncologic outcome is difficult to assess in a short-term time frame, as longer time intervals are necessary to establish true risk reduction. [83-85]

Nonalcoholic Fatty Liver Disease (NAFLD)

Nonalcoholic fatty liver disease (NAFLD) is one of the most common causes of chronic liver disease worldwide, and morbid obesity is strongly associated with its development. [86] NAFLD is subdivided into nonalcoholic fatty liver (NAFL), hepatic steatosis without inflammation, and nonalcoholic steatohepatitis (NASH), which is associated with inflammation and can be indistinguishable histologically from alcoholic steatohepatitis.

The general approach to the overweight or obese patient with NAFLD or NASH is lifestyle modification and weight loss. [87] Histologic improvement has also been observed in some patients with NAFLD or NASH after bariatric surgery. At this time, it is not advised to perform a bariatric operation specifically for the purpose of improving NAFLD or NASH, nor is the optimal bariatric procedure yet identified. Given the potential for worsening fibrosis in some patients following bariatric surgery, patients should continue to have liver function tests monitored closely. [88]

PSYCHOSOCIAL EFFECT AND IMPACT ON QUALITY OF LIFE

Psychological Impact

Effective outcomes following bariatric surgery include psychosocial improvements. [89] There is a general tendency for patients with psychopathologic disorders to improve or normalize after bariatric surgery. [89-93] This may occur because patients take an active role in changing their lives, even while they are still overweight. [94-95]

- A prospective study that included 200 patients undergoing gastric bypass surgery found postoperative improvement at 20, 40, and 92 weeks in health-related (Short-Form 36) and weight-related (Impact of Weight on Quality of Life) quality of life surveys compared with the preoperative responses. [96]
- The Body Shape Questionnaire (BSQ) measures preoccupation with one's body shape and the Shape and Weight Concern subscales of the Eating Disorder Examination-Questionnaire (EDE-Q) assesses dissatisfaction, preoccupation, discomfort, and overvaluation of body shape. For 109 patients undergoing RYGB, responses to BSQ and EDE-Q surveys at 6 months and 12 months after RYGB were improved compared with preoperative responses. [97] In addition, over 80% of female patients had body image scores comparable with published normal values.

There are, at present, no data from prospective studies that assess the psychosocial impact of a sleeve gastrectomy (SG). Based upon the studies that show improvement with weight loss associated with RYGB and AGB, it is reasonable to surmise that patients undergoing a SG would also experience a similar benefit.

However, not all patients experience psychosocial improvement following bariatric surgery. Lack of improved psychosocial function may accompany lack of postoperative weight loss, some may initially improve but later experience declines of function even with maintenance of weight, and others lag behind functioning of normal patients. [89,92,94]

Impact on Quality of Life

Altogether, the improvement of most comorbidities associated with morbid obesity, and the increasing self-esteem based on esthetic reasons, leads to a significant improvement of the quality of life. The patients feel healthier and this has a positive psychological impact. There are many scales available to evaluate quality of life, but all of them coincide in that bariatric

surgery achieves a significant improvement in the quality of life of morbidly obese patients. [92-94]

ABSTRACT

Obesity is increasing all over the world both in developed and underdeveloped countries and is known to be associated with inflammatory changes, insulin resistance and with a hyperlipidemic state. The adipocyte is an important source of adipokines, such as adiponectin, leptin, interleukin (IL)-6 and tumor necrosis factor alpha, and their levels are significantly altered in the plasma of obese patients. Some of these adipokines are known to be associated with dyslipidemia, insulin resistance, vascular dysfunction, and inflammation, and seem to contribute to the development of cardiovascular disease (CVD). Moreover, some inflammatory markers, such as C-reactive protein (CRP), show an independent positive association with body mass index (BMI), and with increased CVD risk.

Cardiovascular morbidity and mortality is associated with the classic risk factors, dyslipidemia, hypertension and impaired glucose metabolism. More recently, inflammatory mechanisms have been accepted as important players in the development of atherosclerotic vascular disease. Obesity, an inflammatory condition, is also an important CVD risk factor.

Recently, it was found that the adipose tissue also expresses hepcidin, and, therefore, may have a direct involvement in iron metabolism. Indeed, obesity is also known to be associated with iron deficiency. The synthesis of hepcidin, an acute phase protein that regulates iron availability, is enhanced in obesity, through IL-6 and leptin secretion by adipose tissue, and may lead to iron deficiency.

Gastric band surgery is a safe surgical procedure for the treatment of morbid obesity, almost without mortality in the perioperative period and a low long-term mortality rate from unrelated causes. Using laparoscopic surgery a gradual, continuous and well-programmed weight loss, is achieved, as well as, a post-operative increasing quality of life and the co-morbidities associated with obesity are also reduced in 75% of patients.

In this book chapter, we will focus on the relationship between obesity, adipose tissue, inflammation and iron metabolism, and we will discuss the impact of gastric banding in the cross-talk between these important factors in obesity.

INTRODUCTION

According to the World Health Organization (WHO), obesity affects 35% of the population, [1] and its prevalence is rapidly increasing worldwide, both in developed and underdeveloped countries. Its development has been associated with genetic and environmental factors. Considering that eating habits, with high caloric diets, sedentary lifestyle and reduced levels of physical activity contribute significantly for weight gain, and that the genetics of populations did not change significantly in the last years, the environmental component appears to be very important for the actual obesity prevalence.

Body mass index (BMI) is a simple index, commonly used to classify underweight, overweight and obesity in adults. According to a recent study, [2] individuals with a BMI of 22.5–25.0 kg/m² had a normal survival, while individuals with moderate (BMI of 30.0–35.0 kg/m²) and extreme obesity (BMI of 40.0–50.0 kg/m²) presented a reduction in life expectancy of 3 and 10 years, respectively. There are several measurements for abdominal adiposity, namely, waist circumference (WC), [3] waist:hip ratio [4] and waist:height ratio. [5] The BMI might be misleading when measuring abdominal adiposity as individuals with a normal BMI may present a large WC. The evaluation of abdominal adiposity is important due to its association with several metabolic dysfunctions, such as, glucose intolerance, reduced insulin sensitivity and adverse lipid profiles.

Actually, obesity, especially abdominal obesity, is considered a strong risk factor for insulin resistance and, as a consequence, for type 2 diabetes *mellitus* (T2DM), [6] as well as, for cardiovascular disease (CVD) events. [7] Obesity has been associated also with inflammatory changes and an hyperlipidemic state, besides insulin resistance, and with an increased risk of CVD events. A hallmark of aging in humans is an increase of adipose mass, especially visceral adipose mass, which is an independent risk factor for chronic heart failure in older people. [8] Moreover, obesity increases the risk of ischemic heart disease, stroke, hypertension, obstructive sleep apnea, degenerative joint conditions, and multiple cancers. [9]

Cardiovascular morbidity and mortality is associated with the classic risk factors, namely dyslipidemia, hypertension and impaired glucose metabolism. However, more recently, inflammatory mechanisms were recognized as playing a vital role in initiation, maintenance and progression of atherosclerotic vascular disease. Atherosclerosis is an inflammatory disease with the participation of leukocytes and several cytokines.

Adipose tissue is an active endocrine organ that secretes several cytokines, known as adipokines. Most of these adipokines are known to interfere with insulin resistance, glucose and lipid metabolism and with the inflammatory process, [10] favoring CVD. Moreover, obesity usually presents a low-grade chronic inflammation, with increased levels of several

pro-inflammatory cytokines and acute phase reactants, such as tumour necrosis factor (TNF)- α , interleukin (IL)-1, IL-6 and C-reactive protein (CRP), that are positively correlated with BMI. [11, 12] Therefore, the prevention of obesity assumes a particular importance in human health, quality of life and longevity.

OBESITY AND ADIPOKINES

Adipokines contribute to appetite regulation and energy expenditure and play an important role in insulin sensitivity, oxidative capacity and lipid uptake. However, in obesity, the amount and characteristics of the adipose tissue is altered, promoting changes in adipokine profile. With obesity, the adipocytes become hypertrophic, inducing hypoxia and an inflammatory response. Moreover, the enhancement of adipose tissue leads to increased macrophage infiltration. Macrophages of the adipose tissue are likely to be an important source of pro-inflammatory cytokines, such as TNF- α and IL-6. [13, 14] It is known that expansion of the adipose tissue during weight gain leads to a recruitment of macrophages into the adipose tissue. [15] Apparently, macrophage infiltration of the white adipose tissue increases with BMI and with adipocyte hypertrophy. [16, 17] The increase in fat mass is associated with alterations in the adipokine profile, favoring hypertension, insulin resistance, dyslipidemia, inflammation and atherogenesis (Figure 1). Herein we will review some of the adipokines, especially their role in inflammation, iron metabolism and CVD risk.

Figure 1. Obesity, adipokine profile and related comorbidities. (AGT, angiotensinogen; IL, interleukin; PAI-1, plasminogen activator inhibitor-1; RBP-4, retinol binding protein-4; SAA, serum amyloid A; TNF- α , tumor necrosis factor- α ; ZAG, zinc- α 2-glycoprotein).

Leptin controls adipose tissue growth via its central nervous system. Leptin controls food intake, by reducing appetite, body weight and fat stores; their blood levels increase with body fat mass. High levels of leptin enhance T-helper (Th)1 immune responses, suppress Th2

immune responses and increase macrophage activity, with production of different cytokines, namely, TNF- α and IL-6, [18] contributing to the low grade inflammatory state, commonly associated with obesity. It also interferes with antioxidant capacity, increasing reactive oxygen-species (ROS) production and inducible nitric oxide-synthase (iNOS) synthesis. Reduction in leptin activity leads to severe insulin resistance and vascular dysfunction. [18, 19] Leptin levels are known to be enhanced in obesity, [20] however, it seems that a resistance to leptin develops, explaining its reduced activity in obesity. [20] Leptin resistance can be explained by several mechanisms, including defects in leptin transport across the blood-brain barrier, impaired neuronal leptin signaling in target neurons or altered signaling in downstream target cells and neurocircuits. [21]

Chemerin is also an adipose tissue cytokine that has been associated with inflammation, adipogenesis, and with glucose and lipid metabolisms. [22, 23] It has a crucial role in adipocyte differentiation and development, and it may act as a modulator of different metabolic pathways in the mature adipocyte. [23, 24] Chemerin appears to act as modulator of the expression of adipocyte genes involved in glucose and lipid homeostasis. [23] Moreover, chemerin has been associated with several metabolic syndrome markers, namely, increased BMI, triglycerides, blood pressure and insulin resistance. [25] Furthermore, it was recently observed that insulin resistance seems to be a predictor of chemerin levels, independently of BMI. [26]

Visfatin is mainly produced by visceral white adipose tissue. Plasma visfatin is increased in subjects with obesity, T2DM, metabolic syndrome and CVD. [27] Circulating visfatin was positively associated with insulin resistance and hyperglycemia. On the other hand, visfatin appears atherogenic because it contributes to leukocyte adhesion [28] and to atherogenic plaque instability, [29] and may have a direct role in vascular dysfunction and inflammation through iNOS upregulation. [30]

Retinol-binding protein-4 (RBP-4), belongs to the lipocalin family, contributes to insulin resistance and it has been reported that it is increased in human obesity, T2DM and in subclinical atherosclerosis. [31] A positive relationship was found with insulin-resistance severity in obesity, with glucose-intolerance and type 2 diabetes, as well as, with a strong family background for T2DM in non-obese subjects. [32, 33] Lipocalin-2, another lipocalin family member, is an adipokine that has a potential role in insulin resistance and atherosclerosis. [31] The gene and protein expressions of lipocalin-2 in visceral adipose tissue is associated positively with inflammation. [34]

Plasminogen activator inhibitor (PAI)-1 is responsible for decreased fibrinolytic capacity and is, therefore, a cardiovascular risk factor. Ma et al. [35] showed that PAI-1 is increased in obesity and may have a direct role in obesity and in insulin resistance.

Serum amyloid A (SAA), an adipokine released primarily by adipocytes, is significantly increased in obesity and is associated with systemic inflammation and atherosclerosis. [36, 37]

Angiotensinogen undergoes two sequential cleavages by renin and angiotensin converting enzyme to produce angiotensin I and angiotensin II, which plays a major role in blood pressure regulation through salt reabsorption in renal tubules and vasoconstriction. Adipose-derived angiotensinogen is substantially increased in obese humans, [38] explaining the relationship between systemic hypertension and obesity.

Apelin is an adipokine with a favourable effect on metabolism, due to its positive effect on blood pressure and cardiac contractility. [39] Its secretion appears to be linked to insulin

secretion; actually, peripheral apelin injection in obese insulin-resistant mice improved insulin sensitivity and glucose uptake in skeletal muscle. [40] However, increased plasma concentrations of apelin were found in obese hyperinsulinemic and T2DM. [41] Moreover, circulating apelin concentration is not correlated to BMI, [42] suggesting that obesity is not the main determinant to increase plasma apelin. Inflammation and oxidative stress may explain the changes in plasma apelin observed in obesity. [41]

Adipocyte-fatty acid binding protein seems to play a crucial role in diabetes and atherosclerotic disease progress; it is, therefore, proposed as a predictor of the metabolic syndrome [43] and of CVD. [44]

Resistin is expressed by cells of the stromal compartment of the adipose tissue, particularly, by macrophages and by peripheral monocytes that are up-regulated during their differentiation to macrophages. It was named for its ability to induce insulin resistance [45] and some studies support also the association of resistin with obesity. [46] High resistin levels are reported to be associated with atherosclerosis, and it has been shown that resistin increases the expression of several pro-inflammatory cytokines, including TNF- α and IL-6. [47] The correlation between BMI and resistin levels [48] is weak; nonetheless, the proportion of mononuclear leucocytes within adipose tissue correlates well with BMI. [15]

The pro-inflammatory state and the impaired immunity in obesity contribute to increase the levels of several cytokines, such as TNF- α and IL-6. TNF- α is known as a key player in inflammatory cell activation and recruitment. [49] It has been linked to insulin resistance in skeletal muscle and adipose tissue, [50] and it seems to favor atherosclerosis through induction of adhesion molecule expression in endothelial and vascular smooth muscle cells. [51] Moreover, TNF- α induces a strong activation of NF-KB (nuclear factor kappa-light-chain-enhancer of activated B cells), a vital transcription factor that regulates an array of genes associated with inflammation. [52] It was reported that obese individuals, as compared with non-obese, present higher blood levels of TNF- α and soluble TNF- α receptors. The subsets of T cell populations and their function may be reduced in human obesity, and this may be related, at least in part, to the increased TNF- α production. [53]

In the absence of inflammation, the adipose tissue seems to contribute to 15–30% of circulating IL-6. [54] IL-6 impairs insulin stimulation, induces liver production of CRP, and associates with obesity-related hypertriglyceridemia by stimulating hepatic secretion of very low-density lipoproteins. [55, 56] The production of CRP, one of the most sensitive markers of inflammation, results from the interaction of pro-inflammatory cytokines (especially, IL-6, TNF- α and IL-1) with their receptors and inhibitors. Raised concentrations of CRP are thought to be emerging risk factors for CVD. [57] CRP levels are also raised in obesity, and weight loss usually leads to a reduction in CRP. [58]

Obesity associates with increased levels of some adipokines, but also with a decrease in the production of others. Adiponectin has anti-inflammatory activity and a protective role against insulin resistance. Adiponectin is inversely associated with the adhesion molecule expression and the transformation of macrophages into foam cells. It seems to protect against metabolic diseases and also against atherosclerosis. [59, 60] However, the protective role for CVD is controversial, with several data reporting a positive association of adiponectin with risk for all-cause and cardiovascular mortality. [61–63] Higher adiponectin levels were strongly associated with a lower risk of impaired glucose metabolism and T2DM, suggesting that adiponectin is involved in their pathophysiology, linking obesity to T2DM. [64] The

obese patients, especially those with visceral obesity, seem to present decreased plasma concentrations of adiponectin. [65, 66] This, suggests the existence of a feedback inhibition process, working when the total body fat mass increases, and inducing an increase in the secretion of other adipokines or a decrease in the metabolic function of the adipocyte. [67]

Omentin is strongly expressed in stromal vascular cells of adipose tissue, and seems to have a role in modulating insulin action. [68] It appears to have anti-inflammatory ability, reducing endothelial dysfunction and atherosclerosis. [69] Obese or overweight individuals have lower plasma omentin levels when compared with lean subjects [70] and its levels are inversely correlated with BMI, WC and circulating leptin. [70, 71] Omentin is also decreased in patients with coronary artery disease. [72]

Zinc- α 2-glycoprotein (ZAG) seems to correlate inversely with markers of obesity such as BMI and WC. [73, 74] Although the factors that down-regulate ZAG are not well understood, obesity-related inflammation could be involved in its regulation. ZAG may act like adiponectin in protecting against the obese state. [75, 76]

Vaspin (visceral adipose tissue-derived serine protease inhibitor) is an adipokine expressed in visceral white adipose tissue. Fat mass expansion has been associated with increased expression of vaspin and its circulating levels. [77, 78] In obese subjects, serum vaspin decreases following a modest weight loss, which is accompanied by improvement in insulin resistance. [79] However, the mechanisms by which vaspin secretion is linked to glucose metabolism and to insulin sensitivity are not entirely understood. Administration of vaspin to obese mice improves glucose tolerance, insulin sensitivity, and reduces food intake. Until now molecular target(s) of vaspin and its mode of action are unknown. [80]

Some adipokines interfere in the regulation of each other's. For instance, TNF- α and IL-6 are involved in the regulation of other adipokines, such as adiponectin; [81] leptin and chemerin production is stimulated by TNF- α . [82]

In summary, in obesity, there is hypoxia, increased macrophage infiltration and adipocytes are hypertrophic and resistant to leptin and insulin action. Although the role of some adipokines is not completely known, the adipokine profile in obesity changes, usually presenting an increase in the levels of leptin, chemerin, visfatin, RBP-4, PAI-1, SAA, angiotensinogen, resistin, TNF- α and IL-6, and a reduction in adiponectin, omentin and ZAG (Figure 1). These changes seem to favor hypertension, insulin resistance, atherogenesis, dyslipidemia and inflammation.

THE IMPACT OF GASTRIC BANDING SURGERY IN OBESITY AND RELATED COMORBIDITIES

According to the current guidelines, bariatric surgery is recommended for patients with a BMI > 40 kg/m² and for patients with a BMI 35-40 kg/m², when presenting serious comorbidities associated with obesity, such as hypertension, diabetes or hypercholesterolemia. [83, 84]

Laparoscopic adjustable gastric banding (LAGB), sleeve gastrectomy and Roux-en-Y gastric bypass are techniques used in bariatric surgery; this surgery has been very successful in morbid obesity as it has been shown to be more effective than lifestyle intervention (physical activity, diet and weight reducing drugs). [85]

Using LAGB surgery a gradual, continuous and well-programmed weight loss, is achieved; moreover, it increases the quality of life of the patients and reduces co-morbidities in over 75% of patients, including the systemic inflammatory response. [86] Laparoscopic surgery, compared with the conventional open method, is mini-invasive and has decreased postoperative pain and length of hospitalization. It is associated with lower rates of complications, lower hospital readmission, and lower mortality. [87, 88]

LAGB is the most common surgery, as it is the easiest surgical technique. It involves the placement of an adjustable gastric band around the upper stomach. The gastric band is connected to an inflatable balloon that can be adjusted by adding or removing saline via a small subcutaneous access port. A loss of 47% excess weight may be maintained for about 15 years, as it shows a substantial long-term weight loss, which is similar to other bariatric procedures. [89] Several studies showed that the laparoscopic gastric band surgery in morbidly obese patients lead to a significant weight loss, [90, 91] even after a short period of one month. [90] Moreover, several authors documented a medium to long-term sustained weight loss with laparoscopic adjustable band gastric. [92-96]

Some authors reported [97] that the other bariatric techniques provide a higher degree of weight loss, however, LAGB seems to be associated with less and fewer severe complications. [98, 99] Significant improvements in health-related quality of life (HRQOL) have been reported, even in the first year after LAGB. [100] A poor baseline HRQOL, a high efficacy of the banding in controlling eat disorders, and a higher weight loss, are believed to be important factors to improve HRQOL of the patients. [100]

Resolution of obesity-related comorbidities depends on significant and sustained weight loss and on excess weight loss. [101, 102] According to Brancatisano et al., [103] weight loss, after Swedish adjustable gastric band placement, is an effective treatment of T2DM in morbidly obese patients. In this case, an early intervention offers the greatest chance of remission. The authors suggested that it might even prevent the occurrence of T2DM in patients with impaired glucose tolerance. [103] Indeed, it was reported that the extensive weight loss in formerly obese women, after Swedish adjustable gastric band surgery, was accompanied by an increase in insulin sensitivity, as showed by fasting insulin and the HOMA index; these favorable metabolic changes were also observed in women after a successful weight loss, by diet alone but were less pronounced. [104] The LAGB induces a substantial sustained positive effect on diabetes in morbidly obese patients, with a significant reduction in glycated hemoglobin (HbA1c) levels and a combined improvement/remission rate of 80%. [105]

THE IMPACT OF LAGB IN ADIPOKINES AND IN THE INFLAMMATORY STATE

As already referred, obesity is characterized by a low grade inflammatory process, involving several inflammatory mediators, produced by the adipose tissue. Conservative weight management techniques, including medication, often fail to achieve substantial and prolonged weight loss and reduction of inflammation in morbid obese individuals, explaining the increase success of bariatric surgery.

Table 1. Main findings reported in studies in obese patients after laparoscopic adjustable gastric banding (LAGB) surgery

Study	Obese Subjects	Follow up after LAGB surgery	Main Findings (*)
Hanusch-Enserer et al. (2004) [121]	18 patients (15 F / 3 M)	6 months	↓ BMI, WC, DBP, SBP, glucose, C-peptide, TG, leptin, insulin
		12 months	↓ BMI, WC, DBP, SBP, C-peptide, TG, GPT, γ -GT, leptin, insulin ↑ ghrelin
Coupaye et al. (2005) [144]	36 women	12 months	↓ fat mass, lean body mass, leptin
Ram et al. (2005) [111]	23 patients (15 F / 8 M)	6 months	↓ BMI, insulin, proinsulin, leptin
		14 months	↓ BMI, insulin, proinsulin, leptin
Diker et al. (2006) [145]	23 patients (15 F / 8 M)	6 months	↓ BMI ↑ adiponectin
		14 months	↓ BMI ↑ adiponectin
Gasteyger et al. (2006) [129]	36 women (premenopausal) LAGB + Swedish LAGB	6 months	↓ BMI, fat, fat free mass, DBP, SBP, glucose, TChol, TG ↑ MCV; No alteration: iron and ferritin
		12 months	↓ BMI, fat, fat free mass, DBP, SBP, glucose, TChol, TG ↑ HDLc, MCV; No alteration: iron and ferritin
		18 months	↓ BMI, fat, fat free mass, DBP, SBP, glucose, TChol, TG, Hb ↑ HDLc; No alteration: iron and ferritin
		24 months	↓ BMI, fat, fat free mass, DBP, SBP, glucose, TChol, TG, Hb ↑ HDLc; No alteration: iron and ferritin
		6 months	↓ BMI, CRP, Orosomucoid ↑ TrSat
Anty et al. (2008) [143]	55 female patients “Roux en Y” gastric bypass + vertical calibrated gastroplasties + LAGB	6 months	↓ BMI, CRP, Orosomucoid ↑ TrSat
Shak et al. (2008) [112]	24 patients (14F / 10M)	6 months	↓ BMI, leptin No alteration: total ghrelin, acylated ghrelin, insulin
		12 months	↓ BMI, leptin No alteration: total ghrelin, acylated ghrelin, insulin

Study	Obese Subjects	Follow up after LAGB surgery	Main Findings (*)	
Komer et al. (2009) [114]	15 patients (11 F / 4 M)	2 weeks	↓ leptin, insulin, glucose, HOMA-IR	No alteration: PYY, ghrelin, GLP-1
		12 weeks	↓ leptin	No alteration: PYY, ghrelin, GLP-1
		26 weeks	↓ leptin, insulin, glucose, HOMA-IR	No alteration: PYY, ghrelin, GLP-1
		52 weeks	↓ leptin, insulin, glucose, HOMA-IR	No alteration: PYY, ghrelin, GLP-1
Moschen et al. (2009) [113]	30 patients (24 F / 6 M)	6 months	↓ BMI, glucose, insulin, HOMA-IR, CRP, TNF-α, leptin, PBEF/Nampt/visfatin	↑ adiponectin, resistin
		12 months	↓ BMI, glucose, insulin, HOMA-IR, CRP, TNF-α, leptin, resistin, PBEF/Nampt/visfatin	↑ adiponectin
Ramalho et al. (2009) [126]	32 women	1 month	↓ BMI, CRP, haptoglobin, transferrin, LDLc, TChol	↑ Alfa-1 antitrypsin, ferritin, sTFR, HDLc
		18 months	↓ BMI, glucose, CRP, haptoglobin, ferritin, sTFR	↑ Alfa-1 antitrypsin, transferrin, LDLc, TChol, HDLc
Trakhtenbroit et al. (2009)106	5 women	3 months	↓ insulin, HOMA-IR	No alteration: glucose
		9 months	↓ insulin, HOMA-IR	No alteration: glucose
		24 months		No alteration: glucose, insulin, HOMA-IR
Moschen et al. (2010) [128]	20 severely patients (13 F / 7 M)	6 months	↓ BMI, glucose, insulin, HOMA-IR, TChol, TG, CRP, IL-6	No detectable: TNF-α
Tussing-Humphreys et al. (2010) [109]	20 women LAGB + LSG	6 months	↓ BMI, WC, sTFR, hepcidin, HOMA-IR, CRP, IL-6, EPO	↑Hb, Ht
Benedix et al. (2011) [146]	Obese patients (7 F / 7 M)	6 months	↓ BMI, glucose, insulin	↑ adiponectin; No alteration: insulin, salivary ghrelin
		12 months	↓ BMI, glucose	↑ adiponectin; No alteration: insulin, salivary ghrelin
Marantos et al. (2011)110	20 women LAGB (13) + LSG (7)	12 months	↓ BMI, leptin, resistin, IL-6	↑ adiponectin
Plum et al. (2011) [107]	8 Obese patients (7 F / 1 M)		↓ BMI, insulin, HOMA-IR, c-peptide, leptin, HDLc	

Table 1. (Continued)

Study	Obese Subjects	Follow up after LAGB surgery	Main Findings (*)
Bradley et al. (2012) [108]	10 patients (9 F / 1 M)	22 ± 7 weeks	↓ BMI, glucose, insulin, HOMA-IR, c-peptide, leptin, CRP
Cugno et al. (2012) [127]	25 women	3 months	↓ BMI, CRP, PAI-1, fibrinogen, VWF
		6 months	↓ BMI, CRP, PAI-1, fibrinogen, VWF
		12 months	↓ BMI, CRP, PAI-1, fibrinogen, VWF
Gelissen et al. (2012) [91]	21 patients (12 F / 9 M)	6 months	↓ BMI, insulin, HOMA-IR;
Hady et al. (2012) [122]	100 patients (66 F / 34 M)	7 days	↓ BMI, insulin,
		1 month	↓ BMI, ghrelin, insulin,
		3 months	↓ BMI, ghrelin, insulin, T Chol, LDL, TG
		6 months	↓ BMI, insulin, T Chol, LDL, TG
Krieger et al. (2012) [115]	30 patients (20 F / 10 M)	12 months	↓ BMI, leptin
Cigdem et al. (2013) [90]	20 patients	1 month	↓ BMI, leptin, orexin-A, insulin resistance
Samaras et al. (2013) [130]	15 patients	2 weeks	↓ BMI, SBP, glucose, insulin, HbA1C, TChol, TG, HDLc, LDLc
		12 weeks	↓ BMI, SBP, glucose, HbA1C, TG
Visockiene et al. (2013) [147]	90 patients (61 F / 29 M)	12 months	↓ BMI, fat mass, glucose, HbA1C, TG
Santos et al. (2014) [86]	46 patients (40 F / 6 M)	3 months	↓ hsCRP, neutrophil count, TG, transferrin

F, female; M, male

BMI, body mass index; CRP, C-reactive protein; DBP, diastolic blood pressure; EPO, erythropoietin; GLP-1, Glucagon-like peptide-1; GPT, glutamic pyruvic transaminase; Hb, hemoglobin; HbA1C, glycated hemoglobin; HDLc, high-density lipoprotein cholesterol; HOMA-IR, homeostasis model assessment of insulin resistance; hsCRP, high-sensitivity CRP; Ht, hematocrit; IL, interleukin; LDLc, low-density lipoprotein cholesterol; LSG, laparoscopic sleeve gastrectomy; MCV, mean corpuscular volume; PAI-1, plasminogen activator inhibitor-1; PBEF, pre-B cell enhancing factor; PYY, peptide YY; SBP, systolic blood pressure; sTfR, soluble transferrin receptor; TChol, Total cholesterol; TG, Triglycerides; TNF- α , tumor necrosis factor- α ; TrSat, transferrin saturation; VWF, von Willebrand factor; WC, waist circumference; γ -GT; γ -glutamyl transferase.

(*) Findings compared to baseline.

In Table 1 are summarized the main findings observed in follow up studies in obese patients, after LAGB surgery.

In general, a marked decrease in weight of morbid obese patients occurs after LAGB surgery. Only a small number of studies focused on the inflammatory profile, adipokines levels or iron status, after LAGB surgery, and most of them provide very limited results. The small sample size is the most frequent limitation of the studies. [106-108] Comparisons between studies are difficult, as they present different periods of follow-up and, sometimes, the follow-up period was insufficient to confirm the long-term effects of bariatric surgery.

Furthermore, some studies cannot be used for comparisons as they included subjects submitted to two different surgery techniques. [109, 110]

Leptin is one of the adipokines that has been studied in obese patients after LAGB surgery. A decrease in leptin levels has been reported, [90, 108, 111-116] as soon as one month after laparoscopic gastric band. [90] Ritt et al. [104] reported that women after Swedish adjustable gastric band, showed a significant reduction in leptin, while TNF- α serum levels increased, compared with dietary-treated obese patients.

Few studies exist concerning the changes induced in the novel adipokines, apelin, resistin, RBP-4, vaspin and visfatin, after bariatric surgery. Inconclusive results are described for resistin concentrations; indeed, obese patients, after LAGB surgery, presented higher resistin levels 6 months after surgery; [113] nevertheless, 12 months after surgery resistin levels decreased significantly. [110, 113]

Botella-Carretero et al. [117] reported an increase in visfatin concentration in obese patients after gastric bypass and biliopancreatic diversion surgery. Plasma visfatin levels are also increased in severely obese patients after intestinal bypass. [118]

In summary, more studies are needed to understand the relationship between weight loss imposed by LAGB and the secretion of adipokines, namely of novel adipokines, by the reduced adipose tissue.

Ghrelin, which stimulates appetite and food intake, enhancing fat mass deposition and weight gain, [119] is down-regulated in obesity. [120] Nevertheless contradictory results are reported concerning ghrelin levels after LAGB surgery; while some authors reported an increase in ghrelin [90, 121] and acylated ghrelin levels, [91] others described lower levels [122] or no alteration in ghrelin [114, 115] and acylated ghrelin [112] concentration.

Surgical injury induces a systemic inflammatory metabolic-endocrine response that is proportional to the severity of the surgical stress. The systemic inflammatory response was evaluated at 6 and 12 hours after laparoscopic adjustable gastric banding (were significantly reduced compared with those) and after open stoma-adjustable silicone band application, and it was reported that the inflammatory response was significantly lower for LAGB. [123]

A positive effect on fibrinolytic function, oxidative stress and antioxidant activity, which are associated to obesity, has been achieved with both open and laparoscopic gastric band interventions. Moreover, postoperative BMI, lipid profile, malondialdehyde (MDA), oxidized low-density lipoprotein (oxLDL), leptin and PAI-1 decreased significantly after both surgeries, while paraoxonase activity increased and was negatively correlated with BMI, MDA, oxLDL, leptin and PAI-1. [116] These studies suggest that several positive effects are observed as a result of weight loss after surgery.

After bariatric surgery, the visceral adipose expression of macrophage and T cell markers, by defining the adipose expression of TNF- α and IL-1 receptor antagonist, contribute to the systemic levels of TNF- α and IL-6. A higher inflammatory state of the

adipose tissue seems to predict a lower BMI reduction after surgery, notably at early stages after surgery. [124]

Indeed, there is some controversial data about the reduction in the inflammatory profile after gastric band surgery; Keogh et al, reported a 40% reduction in CRP levels one year after Swedish adjustable gastric band surgery. [125]

Other studies showed that as soon as 1 month after LAGB surgery, the obese patients present an improvement in the inflammatory profile, with a reduction in CRP and haptoglobin levels [126] that remain low for 18 months after surgery. Cugno et al. [127] observed a reversion of the low-grade inflammation at 3 months after bariatric surgery. Several other studies reported a reduction in the inflammatory process after weight loss by LAGB surgery, as shown by a decrease in CRP [86, 113, 127] and IL-6 levels. [110, 128]

Besides the improvement in the inflammatory state, insulin resistance and adipokine levels, several studies reported an improvement in the lipid profile [122, 129, 130] and in glucose related markers. [111, 113, 114, 121, 128, 130]

OBESITY, IRON STATUS AND THE IMPACT OF LAGB ON IRON METABOLISM

Iron deficiency is the most prevalent worldwide nutritional problem, [131] having significant public health implications. The development of iron deficiency occurs in two stages, starting by depletion of iron stores, followed by depletion of iron containing proteins and enzymes, including hemoglobin, which leads to an overt iron deficiency anemia. Data confirmed an association between obesity and hypoferremia in children, adolescents, adult men and women, and post-menopausal women, in both developed and transitional countries. [132-135] Considering that iron deficiency seems to diminish cognitive function and exercise performance, the association with obesity may represent a poor prognostic for a healthy physical and psychological condition.

The mechanisms that link iron status and obesity are still poorly clarified. The most accepted hypothesis is that iron deficiency is a consequence of the chronic low-grade inflammation state in obesity.

Hepcidin is a major regulator of iron availability for erythropoiesis. It inhibits iron intestinal absorption and reduces the flux of iron from splenic and hepatic macrophages, [136] as it binds to the cellular iron export channel ferroportin-1, present in enterocytes, hepatocytes and macrophages; ferroportin is needed for iron absorption and iron mobilization. The linkage of hepcidin to ferroportin induces ferroportin internalization and degradation, reducing iron availability. [137] The hepatic transcription of hepcidin is up-regulated by pro-inflammatory cytokines, bone morphogenetic proteins (BMP) and iron overload, and is down-regulated by iron deficiency, ineffective erythropoiesis and hypoxia. [138]

Besides the liver, hepcidin is also expressed in other tissues, namely in the adipose tissue. [139] Indeed, data suggest that adipocytes are capable of producing hepcidin, and this production is probably triggered by inflammatory stimuli. [140, 141] It seems that inflammatory changes in the adipose tissue increase hepcidin expression, which might contribute to the erythropoietic disturbances resulting from changes in iron metabolism that could, ultimately, lead to iron deficiency. [141] However, there are still controversies

concerning the contribute of adipocytes to the circulating levels of hepcidin, its importance in obesity and its linkage to erythropoietic disturbances. In healthy individuals, the hepatic hepcidin expression is higher than the adipocyte hepcidin expression; however, in obesity the adipose tissue mass increases and is higher than liver mass; [133] thus, in obesity, the hepcidin secreted by the adipose tissue, may be relevant for iron status and erythropoiesis. Hemojuvelin, which enhances hepcidin expression in the liver, is also expressed in adipocytes and highly increased in adipose tissue from obese. [142] Actually, blood concentrations of soluble hemojuvelin were significantly increased in obese patients, as compared to controls, suggesting that the adipose tissue may have a role in iron homeostasis in obesity and in erythropoiesis. More studies that contribute to clarify the interplay between protein expression-iron status-erythropoiesis are required.

There are few studies concerning the effects of LAGB surgery on iron metabolism. According to Anty et al. [143] bariatric surgery improved iron status in obese patients, as it corrected iron depletion, alongside with the reduction in adipose mass, and inflammation in the patients; Anty et al. [143] also observed a reversion of iron depletion in obese patients 6 months after bariatric surgery; apparently, bariatric surgery improved iron status by reducing chronic inflammation. Actually, they found a significant negative correlation between CRP levels and transferrin saturation; nevertheless, considering that the bariatric surgery included different techniques, namely vertical calibrated gastroplasties, LAGB and “Roux en Y” gastric bypass, it was difficult to analyze the relationship between iron status and the type of bariatric surgery.

Another study, by performing a follow-up of 3 months after LAGB surgery, reported also an increased in iron availability, as shown by an increase transferrin saturation in obese patients. [86]

In opposition to these findings, a follow up study reported that no alterations were observed in iron and ferritin levels 24 months after LAGB. [129]

CONCLUSION

LAGB associates with a successful decrease in body weight, an improvement in inflammatory markers, insulin resistance and lipid profile. Regarding adipokines, LAGB induces a decrease in leptin and an increase in adiponectin levels; however, there is a lack in data studying the effect of LAGB in novel adipokines. Concerning iron bioavailability, further studies are needed to understand the role of the adipose tissue in iron metabolism, in obesity, and the influence of weight loss, imposed by LAGB.

ABSTRACT

Bariatric surgery was developed primarily as a therapy to induce weight loss. Indeed, those with type 2 diabetes were originally not considered surgical candidates due to the perceived high risk nature of surgery in these individuals. However, significant post-operative improvements in diabetes control were noted early in the history of bariatric surgery. Multiple retrospective and prospective studies have since supported this finding, including a number of high quality randomised trials. Variable definitions of diabetes outcomes are used within the published literature complicating comparative analysis. This chapter will review the published literature on glycaemic outcomes at least 12 months following bariatric surgery, and discuss the importance of a consistent set of definitions when reporting on diabetes outcomes.

INTRODUCTION

Bariatric surgery was developed to induce weight loss, and was not originally proposed as a treatment for type 2 diabetes. Indeed, the majority of bariatric surgeons considered a diagnosis of type 2 diabetes to be a contraindication to bariatric surgery, due to a perception of increased surgical risk. Nonetheless, early pioneers of bariatric surgery recognised the early and sustained glycaemic benefits that those with pre-operative type 2 diabetes appeared to gain from surgery. Whilst the mechanism of this effect remains to be completely clarified, the concept of a surgical procedure as an appropriate and effective therapy for type 2 diabetes has been accepted following the publication of an increasing number of studies reporting

superior outcomes in those undergoing surgery when compared to optimal lifestyle and medical treatment. Thus, in 2011, the International Diabetes Federation published a position statement on the place of bariatric surgery in the treatment armory for type 2 diabetes. [1] This concluded by acknowledging that bariatric surgery should be considered earlier in the management of obese persons with type 2 diabetes. In this chapter, we discuss a number of recent studies that have contributed to this opinion.

The published literature on diabetes outcomes following bariatric surgery is extensive, and the quality of study methodology is variable. For the purposes of this chapter, a systematic literature search was performed to capture all studies published up to mid-2014. Search terms included ‘bariatric surgery’, ‘gastric banding’, ‘sleeve gastrectomy’, ‘gastric bypass’, ‘biliopancreatic diversion’, and ‘diabetes’. In addition, the reference lists in included studies along with recent review articles were screened for appropriate studies not detected by the search. [2] Studies of bariatric surgery versus a non-surgical group or alternative bariatric procedures, that reported glycaemic outcomes at least 12 months following surgery were selected for discussion. The design of each of these studies varies, and the list includes prospective randomised controlled studies, and prospective and retrospective case controlled studies. Additionally, a number of meta-analyses including data from smaller, uncontrolled studies are discussed. A summary of the included studies is presented in table 1.

DEFINITION OF DIABETES OUTCOME

The state of diabetes following bariatric surgery and the definition of this has been highly controversial. A number of descriptions of glycaemic outcome to encompass varying degrees of diabetes resolution are utilised within the bariatric surgery literature. However, use of terms such as ‘cure’, ‘resolved’ or ‘remission’ in this context are controversial for a number of reasons. Most importantly, fasting glucose concentrations in the population are a continuous variable and the diagnosis of diabetes itself is based on a somewhat arbitrary threshold above which there is an increased risk of microvascular complications. It is not yet known whether these thresholds remain true in a post-bariatric surgery population, and consequently diagnostic criteria validated for a non-surgical population may be misleading when applied to those who have undergone bariatric surgery. Secondly, the concept of “glycaemic memory” is well established, and relates to the latent effect that periods of hyperglycaemia may have on outcomes later life, irrespective of changes in glycaemic control in the intervening period. [3]

The UKPDS trial illustrated this concept most vividly. Participants randomised to the intensive treatment arm of the study had significantly improved glycaemic control over the 13 years of the study in comparison to those receiving standard treatment. [4] Participants were subsequently followed up 10 years after the completion of the study. Over this 10 year period glycaemic control, as measured using HbA1c, became comparable in the two groups. Despite this those who had been initially randomised to the intensive therapy arm maintained significantly lower rates of microvascular complications and cardiovascular mortality. This strongly argues that the period of early improved glycaemic control had a long term benefit on cardiovascular disease.

Table 1. Summary of discussed studies. Diabetes outcomes reported by each included study are presented, although the reader should note the different definitions utilized

Study	Intervention 1	Intervention 2	Duration of follow up	Study design	Definition of diabetes outcome	Diabetes at baseline (%)		Diabetes outcome at study end (%) based on study specific definition ¹	
						Intervention 1	Intervention 2	Intervention 1	Intervention 2
Hofso [6]	Gastric bypass	Lifestyle	12 months	Prospective case control	Complete = FG <5.6 mmol/L, and 2HrG of <7.8 mmol/L, and HbA1c of < 6.2% (44 mmol/mol) in the absence of glucose lowering therapy. Partial = FG <7.0 mmol/L, and 2HrG<11.1 mmol/L, and HbA1c < 6.5% (47 mmol/mol).	26	29	55 (70) ²	0 (33)
Ikramuddin [7]	Gastric bypass	Lifestyle	12 months	Randomised	HbA1c <7% (53 mmol/L)	100	100	75	32
Kashyap et al [12]	Gastric bypass/ Sleeve gastrectomy	Medical therapy	12 months	Randomised	HbA1c <6.0% (42 mmol/mol)	100	100	44 / 23	6
Lee [9]	Gastric bypass	Sleeve gastrectomy	12 months	Randomised	FG <126 mg/dl (7.0 mmol/L) and HbA1c of <6.5% (47 mmol/mol) in the absence of glucose lowering medications	100	100	93	47

¹ Figures in parentheses represent number achieving partial/incomplete control as per study specific definitions, unless otherwise indicated

² Diabetes outcome inclusive of participants who achieved either complete or partial remission.

Table 1. (Continued)

Study	Intervention 1	Intervention 2	Duration of follow up	Study design	Definition of diabetes outcome	Diabetes at baseline (%)		Diabetes outcome at study end (%) based on study specific definition ³	
						Intervention 1	Intervention 2	Intervention 1	Intervention 2
Schauer [10]	Gastric bypass/sleeve gastrectomy	Lifestyle	12 months	Randomised	HbA1c <42 mmol/mol with or without the use of diabetes medications	100	100	42 / 37 ⁴	12
Scopinaro [11]	Biliopancreatic diversion	Medical therapy	12 months	Prospective historical case control	FG <126mg/dl (7.0 mmol/L) and HbA1c <6.0% (42 mmol/mol) in the absence of glucose lowering medications	100	100	30 (83 ⁵)	0
Serrot [8]	Gastric bypass	Medical therapy	12 months	Retrospective case control	HbA1c <5.7% (39 mmol/mol) in the absence of glucose lowering medications for remission, HbA1c <6.5% (47 mmol/mol) in the absence of glucose lowering medications for control	100	100	24 / 41	NR
Vidal [11]	Gastric bypass	Sleeve gastrectomy	12 months	Prospective comparison	FG <126 mg/dl (7.0 mmol/L), and HbA1c 3.4-5.5% (14-36 mmol/mol) in the absence of glucose lowering medications	100	100	85	85

³ Figures in parentheses represent number achieving partial/incomplete control as per study specific definitions, unless otherwise indicated

⁴ 5/18 in SG arm reported as achieving diabetes remission remained on diabetes medications, whilst none of those in remission in RYGB arm did

⁵ Inclusive of participants who were deemed to have achieved diabetes control defined as an HbA1c <7.0% (53 mmol/mol) in the absence of glucose lowering medication

Study	Intervention 1	Intervention 2	Duration of follow up	Study design	Definition of diabetes outcome	Diabetes at baseline (%)		Diabetes outcome at study end (%) based on study specific definition ⁶	
						Intervention 1	Intervention 2	Intervention 1	Intervention 2
Adams [15]	Gastric bypass	Referred for but did not undergo surgery/ Population control	24 months	Prospective comparison	HbA1c and fasting glucose within the normal reference range	NR	NR	75	7 / 6
Dixon [16]	Laparoscopic adjustable gastric band	Lifestyle	24 months	Randomised	FG <126 mg/dl (7.0 mmol/L) and HbA1c <6.2% (44 mmol/mol) in the absence of glucose lowering therapy	100	100	73	23 ⁷
Kashyap [12]	Gastric bypass / Sleeve gastrectomy	Medical therapy	24 months	Randomised	HbA1c <6.0% (42 mmol/mol)	100	100	33 / 11	6
Leslie [14]	Gastric bypass	Medical therapy	24 months	Retrospective case control	Composite end point of ADA defined treatment goals (HbA1c<7.0% (53 mmol/mol), LDL<100mg/dl, SBP<130mmHg)	100	100	38	17
Mingrone [18]	Gastric bypass/biliopancreatic diversion	Medical/ Lifestyle	24 months	Randomised	FG < 100 mg/dl (5.6 mmol/L) and HbA1c level < 6.5% (45 mmol/mol) for at least 1 year without active pharmacologic therapy	100	100	75 / 95	0

⁶ Figures in parentheses represent number achieving partial/incomplete control as per study specific definitions, unless otherwise indicated

⁷ Assuming that all those not available for follow up at study end (n=4) achieved diabetes remission. Diabetes remission achieved by 11% if each of these participants failed to achieve diabetes remission

¹⁴ Figures in parentheses represent number achieving partial/incomplete control as per study specific definitions, unless otherwise indicated.

¹⁵ Definition not defined in manuscript – implication that remission is defined by fasting and 2 hour OGTT glucose levels below contemporary diagnostic thresholds for dysglycaemia.

¹⁶ Remission rate at 12 months – 120 month figure not provided, although mean HbA1c at that stage was 62 mmol/mol.

¹⁷ Inclusive of gastric banding, sleeve gastrectomy, and gastric bypass.

¹⁸ Medical/lifestyle arm was not standardized.

Therefore it cannot be assumed that if a person with diabetes has “normal” glucose metabolism following bariatric surgery, that their risk of micro and macro vascular disease is the same as a person who has never had a diagnosis of diabetes. It is highly plausible, and indeed worthy of study, that the glucose burden pre bariatric surgery confers an increased risk of micro and macrovascular disease later in life, even if normal glucose levels are restored following surgery. Furthermore, progressive decline in pancreatic beta cell function over time is characteristic of type 2 diabetes and it is unknown whether bariatric surgery alters this process. Thirdly, use of the term “cure” for a chronic disease mediated predominantly by lifestyle may not be helpful in encouraging longer term compliance to favourable dietary and exercise strategies. Regardless of these caveats, a better understanding of glycaemic outcomes following bariatric surgery is important for pre-operative patient counselling as to the likely glycaemic benefits from the procedure.

In the absence of definitive evidence addressing each of the issues above, the literature reporting diabetes outcomes following bariatric surgery is notable for the degree of variability with which diabetes remission is defined. This is confusing, and has possibly contributed to the delays seen for bariatric surgery to be accepted as an appropriate therapeutic option in the management of obese persons with type 2 diabetes. An agreed set of definitions of diabetes outcomes would ideally be used when reporting on bariatric surgery outcomes, and thus the American Diabetes Association (ADA) released a consensus statement in 2009 providing recommendations on the definition of glycaemic outcomes post bariatric surgery.[5] This suggested the use of the terms “partial remission” (HbA1C<6.5% (47 mmol/L), fasting glucose 100-125 mg/dl (5.6 – 6.9 mmol/L)), and “complete remission” (HbA1c “in the normal range”, fasting glucose <100mg/dl (5.6 mmol/L)) provided that each of these assessments were persistent for at least 1 year duration, and in the absence of active pharmacologic therapy or ongoing procedures. Additionally, the ADA defined prolonged remission as the thresholds required for satisfaction of complete remission, maintained for at least 5 years. The definition of diabetes outcomes used by each study discussed below is variable, and the reader is therefore advised to consider the effect the chosen definition may have on outcome interpretation. Furthermore, comparison of bariatric surgery with non-surgical intensive medical management can only rely on achievement of similar glycaemic targets rather than diabetes remission as defined by achieving such glycaemic targets in the absence of glucose lowering therapy.

REVIEW OF DIABETES OUTCOMES FOLLOWING BARIATRIC PROCEDURES

The literature reporting on diabetes outcomes following bariatric surgery is extensive and ranges from small case series through to high quality randomised controlled studies. A number of excellent meta-analyses have attempted to address this diversity of study quality, and some of these publications are discussed later in this chapter. Here, we selected only those studies that included a comparison or control group, either an alternative bariatric procedure or lifestyle/medical therapies, and reported on outcomes at 12 months or beyond.

Studies Reporting Diabetes Outcomes at 12 Months

Gastric Bypass Versus Lifestyle/Medical Therapy

Three studies were identified reporting diabetes outcomes at 12 months following gastric bypass.[6-8] Diabetes control was achieved by 41-75% of those in the gastric bypass arm in these studies. The variability is likely due to differences in the definitions utilised to define diabetes outcomes in each study and in the baseline characteristics of the participants. The study by Ikramuddin and colleagues defined only diabetes control and accepted a higher HbA1c threshold ($<7.0\%$ (53 mmol/mol)) than the other two studies; thus, this study reported the highest rates of diabetes control. The studies by Hofso and Serrot both reported diabetes remission, requiring absence of glucose lowering medications, and control defined by a lower HbA1c level, a higher mean age of participant in the surgical arm (56 vs 42 years), and a higher HbA1c at baseline (8.2 vs 7.1% (66 vs 54 mmol/mol)).

Hofso and colleagues performed a comparison study of gastric bypass versus a lifestyle based intervention in 146 morbidly obese adults (mean BMI 45.6 kg/m²) and reported outcomes at 12 months.[6] The study was not randomised as the study authors considered this to be unethical on the basis of clear local guidelines on selecting bariatric interventions for obese patients. Those in the gastric bypass arm of the study received a low calorie diet for 3 to 6 weeks prior to surgery, and were seen by a dietitian in group sessions every 3 months during the study period. The lifestyle intervention in this study was significant; each participant in this arm was referred to a specialist inpatient weight loss centre and had four stays within the centre during the 12 month study period. Each admission was for between 1 and 4 weeks. Participants received numerous interventions during each stay including input from a medical doctor, a nurse, a physiotherapist, and a specialist trained nurse. Physical activity was increased, and all participants were provided with education on a healthy diet, which they were encouraged to follow. Group sessions focused on the psychosocial and emotional aspects of obesity and weight loss. Weight loss drugs were not used. Phone contact was maintained fortnightly while participants were away from the weight loss centre. In addition to fasting bloods, a 75g 2 hour oral glucose tolerance test was used to define both diabetes at study entry and diabetes outcomes. 26% and 29% of participants in the gastric bypass and lifestyle intervention arms respectively had type 2 diabetes at baseline. Diabetes remission was defined as a fasting glucose <5.6 mmol/L, and a 2 hour glucose of <7.8 mmol/L, and an HbA1c of $<6.2\%$ (44 mmol/mol) in the absence of glucose lowering therapy. In addition, the study authors defined partial diabetes remission as glucose levels below the diagnostic thresholds at baseline (<7.0 and 11.1 mmol/L for fasting and 2 hour glucose respectively) and an HbA1c $<6.5\%$ (47 mmol/mol) without the use of glucose lowering therapy.

The study authors elected to report diabetes remission rates at 12 months, including participants who had achieved either complete or partial remission. Thus, the overall diabetes remission rate by this criteria was significantly greater in the gastric bypass arm versus those in the lifestyle intervention arm (70 vs 33%, OR 4.7 (1.2–18.4). However, none of the participants in the lifestyle intervention arm achieved complete diabetes remission, whilst 11 out of the 14 participants (55% of those with type 2 diabetes at baseline) achieved complete diabetes remission at 12 months follow up.

Ikramuddin and colleagues performed a 12 month randomised study of intensive medical management versus intensive medical management plus Roux-en-Y gastric bypass.[7] 120 obese participants (BMI 30-39 kg/m²) with type 2 diabetes were recruited, and a primary composite outcome incorporating achievement of diabetes, blood pressure and lipid control targets was reported. Intensive medical management included a reduced energy diet for all participants with the aim of weight loss in the order of 1-2 pounds per week. Increased physical activity was encouraged, and each participant had regular face to face contact with a study interventionist to discuss behavioural and social issues around weight loss. Orlistat, and Sibutramine prior to withdrawal from the US market, were available for use by those in the lifestyle arm if agreed weight loss targets were not met. The contemporary American Diabetes Association guidelines for the management of type 2 diabetes were followed for the medical management of each participant in the study. 75% of those randomised to gastric bypass achieved diabetes control (defined solely as an HbA1c of <7% (53 mmol/L)) at 12 months versus 32% of those randomised to intensive medical management only (OR, 6.0; 95% CI, 2.6-13.9). Whilst the primary composite outcome was achieved in 49% (versus 19%) of those undergoing gastric bypass, there was no difference between the two arms when blood pressure and lipid outcomes were assessed as independent outcomes.

Serrot and colleagues performed a retrospective case control study of obese (BMI 30-35 kg/m²) participants with type 2 diabetes who had undergone gastric bypass in their institution versus a control group (BMI matched persons with type 2 diabetes from a primary care database).[8] Of nearly 3000 gastric bypass procedures performed over an 8 year period, 20% had preoperative type 2 diabetes and of these, 17 participants had a BMI of 30-35 kg/m². Each surgical participant was matched with one control subject. Diabetes remission was defined as an HbA1c <5.7% (39 mmol/mol) in the absence of glucose lowering medications, whilst diabetes control was defined as an HbA1c <6.5% (47 mmol/mol) in the absence of glucose lowering medications. At the 12 month follow up assessment 4/17 (24%) of surgical participants had achieved diabetes remission and a further 7 (41%) of participants had achieved diabetes control. Classification outcomes in the control group were not reported. The mean HbA1c in those who had undergone surgery fell from a baseline level of 8.2% ((66 mmol/mol) $\pm$ 2.0%) to 6.1% ((43 mmol/mol) $\pm$ 2.7%), but did not change significantly in the control group ((7.0 (53 mmol/mol) $\pm$ 0.7% to 7.1 (54 mmol/mol) $\pm$ 1.8%).

Gastric Bypass Versus Sleeve Gastrectomy

Two randomised controlled studies and one prospective non-randomised study reported outcomes at 12 months following either gastric bypass or sleeve gastrectomy, with 2 of these studies including a lifestyle/medical arm.[9-11] In addition, a further randomised controlled study primarily reporting on 24 month outcomes, presented 12 month outcomes.[12] Whilst each study used stringent criteria for diabetes remission/control, it should be noted that participants in the study by Lee and colleagues demonstrating superior efficacy of GBP compared to SG, these participants were Taiwanese and had significantly lower BMI at baseline versus those in the studies by Schauer and Vidal which both showed similar efficacy of GBP compared to SG. The apparent marked increase in surgical participants achieving diabetes remission in the study by Vidal when compared to those in the study by Schauer (85% versus 40%) is of interest. Despite a similar age at surgery (mean approximately 48 years), participants in the Schauer study were not as obese, had a longer pre-operative

duration of diabetes, and a 4 fold higher pre-operative use of insulin. This may indicate less beta cell reserve, and thus reduced likelihood of resolution of diabetes even with substantive weight loss and improved insulin sensitivity.

Lee and colleagues reported 12 month diabetes outcomes following randomisation to gastric bypass or sleeve gastrectomy in 60 overweight (BMI 25-35 kg/m²) Taiwanese participants with sub-optimally controlled type 2 diabetes.[9] Diabetes remission was defined as a fasting glucose of <126 mg/dl (7.0 mmol/L) and HbA1c of <6.5% (47 mmol/mol) and the absence of diabetes medications. Participants were assessed by an extensive multidisciplinary team prior to surgery but the study does not report on medical interventions used in the post-operative period. 93% of those randomised to gastric bypass achieved diabetes remission at 12 months versus 47% of those who had undergone sleeve gastrectomy.

Schauer and colleagues first reported on diabetes outcomes of overweight and obese American participants (BMI 27-43 kg/m²) and type 2 diabetes at 12 months of follow up.[10] 150 participants were recruited and randomised in equal numbers to one of 3 interventional arms (intensive medical therapy, gastric bypass plus intensive medical management, and sleeve gastrectomy plus intensive medical management). Diabetes control/remission, defined as an HbA1c <42 mmol/mol with or without the use of diabetes medications, was achieved by 12% of those randomised to medical therapy only, 42% of those randomised to the gastric bypass arm, and 37% of those randomised to the sleeve gastrectomy arm. The definition of diabetes remission utilised for this study was clearly limited by the acceptance of an HbA1c < 42 mmol/mol as evidence for remission even in the context of ongoing diabetes medication use. It could be argued that those who required ongoing glucose lowering therapy should be defined as being, at best, partial responders. However, all of those in the gastric bypass arm who achieved diabetes remission did so without the ongoing use of diabetes medications, whilst 28% of those in the sleeve gastrectomy arm who were reported as achieving diabetes remission continued to require glucose lowering therapy; all of those in the medical management alone arm who achieved the primary endpoint remained on glucose lowering therapy.

Vidal and colleagues performed a non-randomised prospective study comparing outcomes of severely obese (BMI >35kg/m²) participants with type 2 diabetes (n=91) who underwent either gastric bypass (n=52) or laparoscopic sleeve gastrectomy (n=39).[11] The groups were matched at baseline for duration, control, and treatment of diabetes. Diabetes remission was defined as a fasting glucose <126 mg/dl (7.0 mmol/L) and an HbA1c within the normal range (3.4-5.5% (14-37 mmol/mol)) in the absence of glucose lowering medications. At 12 months following surgery diabetes remission had been achieved by 84.6% of those who had undergone gastric bypass and 84.6% of those who had undergone laparoscopic sleeve gastrectomy. Interestingly, the study authors found no relationship between weight loss and diabetes remission, but did note a significant association between duration and severity (treatments required, HbA1c at baseline) of diabetes and diabetes remission.

Biliopancreatic Diversion Versus Lifestyle/Medical Therapy

Scopinaro and colleagues performed a prospective, case controlled study of biliopancreatic diversion surgery versus medical management in overweight or obese persons (BMI 25-34.9 kg/m²) with type 2 diabetes.[13] Participants who underwent biliopancreatic

diversion surgery had a mean age of 56 years and established diabetes (mean duration of diabetes = 11 years, mean HbA1c at baseline = 78 mmol/mol, 12/30 participants requiring insulin therapy at baseline). Controls were selected from an historical registry. The study authors defined 3 categories of diabetes outcomes. Diabetes remission was defined as a fasting glucose <126 mg/dl (7.0 mmol/L), and an HbA1c $\leq$ 6.0% (42 mmol/mol) without the use of glucose lowering medications; controlled diabetes was defined as an HbA1c $\leq$ 7.0% (53 mmol/mol) in the absence of glucose lowering medication; improved diabetes was defined as a >1% (10-11 mmol/mol) reduction in HbA1c levels when compared to baseline. No participants in the historical control group achieved diabetes remission or diabetes control during 1 year of treatment (mean HbA1c at baseline = 8.8% (73 mmol/mol)). Whilst two thirds of participants required an increase in their medication doses during this 12 month period, no participant was able to reduce medication doses. In contrast, diabetes remission was achieved by 30% of those who had undergone biliopancreatic diversion, and diabetes control by a further 53% (83% total). However, 5 participants (out of 12) who required insulin therapy at baseline remained on insulin therapy at 12 months following biliopancreatic surgery.

The relative low rate of diabetes remission following biliopancreatic diversion in this study, in contrast to very high rates more commonly reported following this procedure, may be explained by the baseline characteristics of the study cohort. Specifically, this was an older cohort than other studies discussed above (mean age = 56.4 years), and participants had both a longer duration of diabetes (mean = 11.2 years) and a higher HbA1c (mean = 9.6% (81 mmol/mol)) at baseline.

Studies Reporting on Outcomes from 12 to 24 Months

Gastric Bypass Versus Lifestyle/Medical Therapy

Two study of gastric bypass versus lifestyle medical therapy were identified that reported on outcomes at 24 months.[14,15] The study by Adams and colleagues continued to follow up their cohort for a total of 72 months and is therefore discussed in the following section. Leslie and colleagues performed a retrospective case control study of outcomes following gastric bypass versus medical managements for obese persons with type 2 diabetes.[14] Rather than define diabetes outcomes using simply glycaemic markers, the study authors elected to use a composite end point of treatment goals as recommended by the American Diabetes Association for the management of type 2 diabetes (HbA1c <7.0% (53 mmol/mol), low-density lipoprotein <100mg/dl, systolic blood pressure <130mmHg). 152 and 115 participants who had undergone gastric bypass or medical therapy alone respectively were included in the analysis. The percentage of participants satisfying the ADA treatment goals who had undergone gastric bypass was 10.5% at baseline, increasing to 38.2% at 24 months follow up. A smaller, non-significant increase was noted in the medical therapy group (13.9% at baseline versus 17.4% at 24 months).

Laparoscopic Adjustable Gastric Band Versus Lifestyle/Medical Therapy

One study was identified that reported on diabetes outcomes 24 months following laparoscopic adjustable gastric banding. Dixon and colleagues reported diabetes outcomes at

24 months on 60 obese participants (BMI 30-40 kg/m², age range 20-60 years) with type 2 diabetes randomised to either laparoscopic adjustable gastric banding or an intensive lifestyle program without the use of bariatric surgery.[16] The lifestyle program was comprehensive and administered via a multidisciplinary team consisting of a physician, dietitian, and diabetes nurse via face to face meetings at 6 week intervals. A low energy diet with reduced saturated fats was prescribed along with increased exercise activity; very low calorie diets and/or weight loss pharmaceutical agents were also available for use. Diabetes remission was defined as a fasting glucose level of <126 mg/dl (7.0 mmol/L) and an HbA1c <6.2% (44 mmol/mol) in the absence of glucose lowering therapy, and was achieved by 73% of those who in the laparoscopic adjustable gastric band arm versus 11-23% (based on the assumption that diabetes remission was/was not achieved by 4 participants randomised to the lifestyle arm who did not complete the study). Furthermore, improvement in diabetes control was evident in those who underwent gastric banding with 26/30 participants not requiring glucose lowering therapy at study end (versus 2 at baseline).

The percentage of participants who achieved diabetes remission in the surgical arm of this study was high, and particularly notable given that the mean age at which participants underwent surgery (46.6 years), the mean HbA1c at baseline (7.8% (62 mmol/mol)), and a mean BMI at surgery (37.0 kg/m²) was comparable to baseline characteristics of cohorts in other studies discussed in this chapter following gastric bypass or biliopancreatic diversion surgery. However, only one participant in the surgical group used insulin therapy at baseline, and although duration of diabetes at surgery was not reported, the exclusion of participants with evidence of microvascular complications is likely to result in the selection of those with a more recent diagnosis of diabetes.

Bariatric Surgery Versus Lifestyle/Medical Therapy

Three studies were identified that reported on outcomes in studies incorporating two or more bariatric surgery modalities.[12,17,18] The Swedish Obesity Study (SOS) reported on outcomes at 24 months in addition to those at 120 months and is thus discussed in the section below.[17] The studies by Kashyap and Mingrone both included a gastric bypass arm but reported markedly different diabetes outcomes at 24 months (33 versus 75% respectively). The authors used significantly different definitions of diabetes outcomes that could potentially result in discordant outcomes. However, whilst Kashyap elected to simply use HbA1c, Mingrone utilised seemingly more stringent criteria including a fasting glucose and HbA1c threshold, and the absence of glucose lowering medication. It should be noted though that Mingrone accepted an HbA1c of <6.5% (47 mmol/mol) as evidence of diabetes remission. The discordance between these studies is also not easily explained by differing baseline characteristics; whilst the two cohorts undergoing gastric bypass were of similar ages at operation (mean = 47.9 years and 43.9 years for the Kashyap and Mingrone studies respectively), and had a similar duration and control of diabetes at baseline (7.4/6.0 years, 9.0%(75 mmol/mol)/8.5%(69 mmol/mol) respectively), participants in the Mingrone study had a significantly higher BMI (44.6 versus 36.1 kg/m²). Additionally, differences in the medical/lifestyle program, prescribed for those in the surgical arms alongside surgery, do not appear likely to be a factor in this anomaly. None of the medical/lifestyle arm of the Mingrone study achieved diabetes remission, in comparison to 6% of participants in the equivalent arm of the Kashyap study.

Kashyap and colleagues undertook a prospective randomised study of optimal medical therapy versus either gastric bypass or sleeve gastrectomy in 60 moderately obese (mean BMI =36.1 kg/m²) participants with type 2 diabetes at baseline.[12] All patients received intensive medical therapy as recommended by the American Diabetes Association, including dietary modifications, increased frequency of capillary glucose measurements, and the use of all available glucose lowering agents. In addition, each participant received nutritional counselling by a study dietitian and underwent a psychological assessment, in part to assess suitability for bariatric surgery. Participants were then randomly allocated to either ongoing medical therapy alone, gastric bypass surgery, or sleeve gastrectomy. Diabetes remission was defined as an HbA1c of less than 42 mmol/mol (6.0%). 44% and 26% of those who had undergone gastric bypass and sleeve gastrectomy respectively had an HbA1c of <6.0% (42 mmol/mol) at 12 months follow up, compared with 6% of those who had received medical therapy alone. However, a reduction in the number of participants satisfying criteria for diabetes control at 24 months was evident (33, 11, and 6% for gastric bypass, sleeve gastrectomy, and medical therapy respectively).

Mingrone and colleagues performed a single centre randomised controlled study of gastric bypass versus biliopancreatic diversion versus medical/lifestyle therapy only.[18] 60 participants (age 30-60, BMI >35 kg/m²) were recruited, each of whom had had type 2 diabetes for at least 5 years and had a current HbA1c of >7.0% (53 mmol/mol). Each participant had visits with a multidisciplinary team (including a diabetologist, dietitian, and study nurse) at baseline and then 1, 3, 6, 9, 12 and 24 months following commencement of the intervention. A low-fat, high fibre diet and ≥30 minutes of brisk walking every day was prescribed to those in the medical arm and diabetes medications were adjusted based on regular HbA1c measurements. In keeping with the definition suggested by the American Diabetes Association, diabetes remission was defined as a fasting plasma glucose level < 100 mg/dl (5.6 mmol/L) and an HbA1c level < 6.5% (45 mmol/mol) for at least 1 year without active pharmacologic therapy. Diabetes remission was achieved by 95% of those in the biliopancreatic diversion arm, 75% of those in the gastric bypass arm, and none of those in the medical arm. Biliopancreatic diversion and gastric bypass were associated with an odds ratio of diabetes remission of at least 9.5 (95% CI, 2.54 to 35.51; P<0.001) and 7.5 (95% CI 1.97 to 28.61; P<0.001) respectively when compared with medical therapy alone.

As noted earlier, the 95% diabetes remission rate in the biliopancreatic diversion arm of the above study by Mingrone and colleagues is significantly higher than the 30% at 12 months seen in the study by Scopinaro discussed in the section above. Again, this is likely to be explained by the older age at surgery, and longer duration of diabetes of participants in the Scopinaro study.

Studies Reporting on Outcomes Beyond 2 Years

Bariatric Surgery Versus Lifestyle/Medical Therapy

Adams and colleagues performed a prospective study recruiting obese adults (BMI>35kg/m²) who underwent gastric bypass surgery over a 10 year period (n=418).[15] 2 control groups were included, the first of which included participants who had sought but not undergone gastric bypass surgery (n=417), and a second group comprised of obese adults

selected from a regional registry (n=321). An explanation as to why each of the participants in the first control group had not undergone gastric bypass was not provided in the manuscript. The prevalence of diabetes within each group at baseline was not presented, although the mean HbA1c was 42 mmol/mol or less in each group. Diabetes at baseline was defined as a fasting glucose of >126mg/dl (7.0 mmol/l), and/or an HbA1c of >6.5% (47 mmol/mol), and/or the use of glucose lowering medications, whilst remission of diabetes was defined as an HbA1c and fasting glucose within the normal reference range (absolute figures not provided) in the absence of ongoing glucose lowering therapy. Using these definitions, diabetes remission was achieved by 75% (95% CI, 63%-87%) and 62% (95% CI, 49%-75%) at 2 and 6 years post-surgery respectively in the gastric bypass group. Diabetes remission rates at 6 years were significantly lower in those who had either sought gastric bypass but not undergone surgery (8%; 95%CI,0%-16%, OR, 16.5 versus gastric bypass) and population controls (6%; 95% CI, 0%-13%, OR, 21.5). The study authors also noted a significantly lower incidence of new diagnoses of diabetes during 6 year follow up in the gastric bypass group (2%; 95% CI, 0%-4%) in comparison to those in the first control group (17%; 95% CI 10%-24%, OR 0.11 favouring gastric bypass; 95% CI 0.04- 0.34) and those in the population control group (15%; 95% CI 9%- 21%, OR 0.21 favouring gastric bypass; 95% CI, 0.06-0.67).

Iaconelli and colleagues performed a prospective case controlled study of conventional lifestyle and medical therapy versus biliopancreatic diversion in obese participants with type 2 diabetes.[19] Diabetes outcomes were reported at 10 years. The study authors note the initial study design of a randomised controlled trial was declined by their ethics regulatory committee partly on the basis of the required long duration of follow up. Instead the study team enrolled 110 obese participants with type 2 diabetes and initiated a 3 month run-in intervention comprising dietary optimisation. At the end of the run-in period, participants who met the inclusion criteria for the study (age 25-60 years, BMI >35 kg/m², and a residual diagnosis of type 2 diabetes on the basis of standard criteria, n=50) were offered either conventional lifestyle and medical therapy alone, or conventional therapy plus biliopancreatic diversion surgery (n=28 and 22 respectively). Conventional therapy included dietary, exercise and medication optimisation as per current American Diabetes Association guidelines. Diabetes remission was actually a secondary endpoint in the study, with the authors choosing instead change in the glomerular filtration rate from baseline to study end as their primary endpoint. The authors did not specify the definition used for diabetes remission in the study, although it is implied that diagnostic thresholds commonly used at the initiation of the study (fasting glucose >7.0 mmol/L (on 2 occasions) and/or a 2 hour glucose > 11.1 mmol/L following a 75g oral glucose tolerance test) were utilised to assess diabetes outcome. The manuscript provides no information on whether ongoing use of glucose lowering therapy was accounted for. Allowing for these limitations, diabetes remission was achieved by 100% of participants at 12 months by those who had undergone biliopancreatic diversion surgery; the authors noted that none of these participants redeveloped diabetes during the remainder of follow up to 10 years. The mean HbA1c at 10 years in the conventional treatment and biliopancreatic diversion surgery arms was 7.8% (62 mmol/mol) and 4.9% (30 mmol/mol) respectively.

Pontiroli and colleagues performed a prospective case controlled study of outcomes following laparoscopic adjustable gastric banding versus optimisation of lifestyle and medical therapies.[20] The study investigators recruited 122 sequential patients (age range 18-66)

referred for the management of obesity, who met contemporary criteria for bariatric surgery (BMI > 40 kg/m², or BMI > 35 kg/m² in the presence of obesity related co-morbidities). The absence or presence of type 2 diabetes was clarified through an oral glucose tolerance test based on standard diagnostic criteria. The participants were then followed within two intervention studies; the primary intervention study assessed the effect of laparoscopic adjustable gastric banding on the prevention of type 2 diabetes, whilst the secondary intervention study assessed the effect on those with established type 2 diabetes. Thus, 37 participants with established type 2 diabetes were enrolled in the secondary intervention section of the study. Each of these participants was offered laparoscopic adjustable gastric banding; 17 consented to surgery with the remainder wishing to utilise lifestyle/medical options. The applied definition of diabetes remission was not specifically provided in the published manuscript, although it is implied that contemporary diagnostic criteria for the diagnosis of thresholds of dysglycaemia were utilised. Thus, diabetes remission would be diagnosed on the basis of a fasting glucose level <6.1 mmol/L, and a 2 hour post glucose level of <7.8 mmol/L (presumably also in the absence of glucose lowering medications). HbA1c measurements were recorded but are not specifically reported in the context of diabetes remission. Using this definition, diabetes remission was achieved by 45% at 4 years by those who had undergone laparoscopic adjustable gastric banding, and 4% of those who had declined surgery. Of note, none of those who had undergone laparoscopic adjustable gastric banding as a part of the primary prevention component of the study developed diabetes during the 4 years of follow up, whilst 17% of those who declined surgery did so.

Studies Comparing Different Forms of Bariatric Surgery

Pinheiro and colleagues performed a randomised study of two types of Roux-en-Y gastric bypass in 105 participants with type 2 diabetes and severe obesity (BMI >50kg/m²).^[21] The diagnosis of diabetes and diabetes outcomes was defined on the basis of diagnostic thresholds. The primary intent of the study was to assess the varying effect of the resulting length of both the biliary and Roux limb of the gastric bypass. In group 1, the biliary and Roux limbs were 50 and 150 cm respectively, whilst in group 2 the biliary and Roux limbs were 100 and 250cm respectively (so called long-long limb Roux-en-Y gastric bypass). At 48 months follow up, diabetes control (glycaemic markers below diabetes diagnostic thresholds in the absence of glucose lowering medication) was achieved in 58% of those in group 1 and 93% of those in group 2. A statistically higher proportion of participants in group 2 had improvement of dyslipidaemia, whilst there was no difference in the improvement in hypertension seen.

Pournaras et al performed a prospective comparison study of gastric bypass (n=22) versus gastric banding (n=12) in severely obese participants with type 2 diabetes.^[22] The study design allowed for an assessment of diabetes outcomes, along with exploration of the mechanism underlying the expected improvements in diabetes control. The study investigators defined diabetes remission based on contemporary diagnostic thresholds; a fasting plasma glucose <7 mmol/L in the absence of medical treatment for at least 3 days, and a 2-hour plasma glucose <11.1 mmol/L following an oral glucose tolerance test (OGTT). In addition, an HbA1c <6.0% (42 mmol/mol) after 3 months without the use of glucose lowering medication was required. Participants had established diabetes at baseline with a mean

duration of diabetes of >5 years; 55% of those who underwent gastric bypass and 30% of those who underwent gastric banding required insulin therapy prior to surgery. 68% of those in the gastric bypass arm had achieved diabetes remission at 12 months of follow up versus none in the gastric banding arm despite similar weight loss (20-25% body weight) at that assessment. At 36 months follow up, the percentage of those in diabetes remission had increased to 72% and 17% for gastric bypass and gastric banding respectively.

Following publication of diabetes outcome results after bariatric surgery at 12 months,[10] Schauer and colleagues performed a further analysis of follow up outcomes at 36 months.[23] 137 (91%) of the original 150 randomised participants (randomised in equal numbers to intensive medical therapy, gastric bypass plus intensive medical therapy, and sleeve gastrectomy plus intensive medical therapy) were evaluated. As in the original study, diabetes remission was defined as an HbA1c of <42 mmol/mol with or without the use of diabetes medications, and was achieved by 38% and 24% of those who had undergone gastric bypass and sleeve gastrectomy respectively (versus 5% of those randomised to intensive medical therapy alone). Glycaemic relapse (defined as satisfying criteria for diabetes remission at 12 months but not at 36 months) was seen in 80% of participants in the medical therapy group, 24% of those who had undergone gastric bypass group, and 50% of those who had undergone sleeve gastrectomy. Decrease in BMI following surgery (odds ratio, 1.33 for every 1 unit (mg/m²); 95% CI, 1.15 to 1.56; P<0.001) and the pre-surgical duration of type 2 diabetes (duration <8 versus >8 years; odds ratio, 3.3; 95% CI, 1.2 to 9.1; P = 0.02) were the only two predictors of diabetes outcome following either bariatric surgery.

The Swedish Obese Subjects Study (SOS study) was a very large prospective non-randomised study performed in Sweden between 1987 and 2000.[17] Following a large scale national recruitment drive, 4047 participants who met the study criteria (BMI >34 kg/m² for men, BMI >38 kg/m² for women, age 37-60 years) were recruited and offered either non-surgical or, if appropriate, surgical interventions. Surgery was performed at 25 national centres and included gastric banding, sleeve gastrectomy, and gastric bypass. Each participant who had chosen bariatric surgery was matched at the time of surgery to a participant who had elected medical therapy only (based on 18 variables including demographic, metabolic, psychosocial, and personality parameters). Medical and lifestyle therapies were not standardised for this trial. The intervention for both the surgically treated participant, and their match medical therapy only control, was considered to have commenced on the day of surgery.

Outcomes following 10 years of follow up were reported in 2004 and included data on 4047 participants with at least 2 years of follow up data available (all those enrolled in the SOS study) and 1703 participants who had 10 years of follow up data available. The study authors reported both diabetes incidence (compared with baseline) and diabetes outcomes. The majority of enrolled participants did not have type 2 diabetes at baseline, although the study authors were still able to report on approximately 200 participants who did and had follow up data extending to 10 years. The criteria used to define both disease and disease outcome were the same, and were reflective of contemporary diabetes diagnostic thresholds. Thus, diabetes remission was defined as a fasting glucose of <7.0 mmol/L (126 mg/dl) in the absence of glucose lowering medications.

590/4047 and 202/4047 participants had type 2 diabetes at baseline and 2 or 10 years of follow up data available respectively. Of those with 2 years of follow up data, 246/342 (72%) of surgical participants and 52/248 (21%) of control participants had achieved diabetes

remission (Odds ratio 8.42 95%CI 5.68-12.5). Over the same period, 8% of control participants who did not have diabetes at baseline (n=1402) developed type 2 diabetes, compared to 1% of those who had undergone bariatric surgery (n=1489). Of those with 10 years of follow up data, 42/118 (36%) of surgical participants and 11/84 (13%) of control subjects had achieved diabetes remission (Odds ratio 3.45 95%CI 1.64-7.28). As expected the incidence of new diabetes in those who did not have type 2 diabetes at baseline, had increased further at 10 years such that 24% and 7% of control and surgical participants respectively had developed diabetes.

Recently, the SOS study authors have reported on further long term outcomes at greater than 15 years.[31] These data provide further evidence that bariatric surgery has a favourable and durable effect on obesity and the risk of developing type 2 diabetes or related complications. Surgery reduced the risk of developing type 2 diabetes by 78% at 15 years, and reduced overall mortality by 29% (HR=0.71, 95%CI 0.54-0.92) at 16 years of follow up. Bariatric surgery was associated with a 53% reduction in the risk of fatal cardiovascular events (adjusted HR=0.47, 95%CI 0.29-0.78), and a 33% reduction in total cardiovascular events (HR=0.67, 95%CI 0.54-0.83) at up to 18 years of follow up. A reduction in the incidence of a new diagnosis of cancer following surgery (HR=0.67, 95%CI 0.53-0.85) was also demonstrated. On the basis that obesity is a known risk factor for cancer, this raises the possibility that intentional weight loss achieved by bariatric surgery may protect against this association although further research is required.

META-ANALYSES OF STUDIES REPORTING ON DIABETES OUTCOMES FOLLOWING BARIATRIC SURGERY

A large number of meta-analyses using a diverse range of selection criteria have been published. The majority report on weight or short term outcomes only and are therefore beyond the scope of this chapter. The reader is directed towards meta-analyses performed by Lai, Maggard-Gibbons, and Gloy and colleagues which all included either studies discussed in the paragraphs above, or studies reporting on diabetes outcomes <12 months following surgery.[24-26] In addition, Parikh and colleagues have recently published a meta-analysis of 39 studies reporting on diabetes outcomes in subjects with a BMI <35kg/m². [27]

The largest meta-analysis thus far published reporting outcomes of bariatric surgery (gastric banding, gastroplasty, RYGB and biliopancreatic diversion/duodenal switch (BD/DS)) included all studies published between 1990 and 2006, and updated a previous meta-analysis by the same group.[28,29] The meta-analysis included 621 studies, within which 103 arms specifically reported on diabetes outcomes (3188 subjects). All study designs were included, with each study was assigned a level of evidence. 22.3% of the cohort (30,160/135,246 subjects) had pre-operative diabetes. Weight loss across the whole cohort, expressed as excess body weight lost (EBWL%), was 48.98, 56.48, 63.25, and 73.72% at ≥ 2 year follow up for gastric banding, gastroplasty, RYGB, and BD/DS respectively, although the majority of subjects remained obese (Mean pre-operative BMI 47.86, mean post-operative BMI 33.89kg/m²). Weight loss assessed at ≥ 2 years exceeded that reported at shorter post-operative intervals for each modality. Weight loss in patients with pre-operative diabetes was similar with 67.1 and 58.01% EBWL at <2 or ≥ 2 year follow up respectively when all

surgical modalities were included (67.10 and 64.7% for RYGB specifically). Analysis of the subjects with diabetes included in the meta-analysis revealed that resolution of diabetes (defined as cessation of diabetes medications and either normal fasting glucose (<100 mg/dl (5.5 mmol/L)) or an HbA1c $< 6\%$ (42 mmol/mol) across the whole cohort was 78.1% (80.27 and 74.59% at <2 and ≥ 2 year follow up respectively), whilst resolution or improvement (defined as a reduction in number or dose of diabetes medications, or an improvement in fasting glucose to between 100-125 mg/dl (5.5 - 6.9 mmol/L)) was seen in 86.61% (86.0 and 87.24% respectively). Further assessment based on surgical procedure revealed that resolution of diabetes was seen in 56.73% (54.99 and 58.29% at <2 and ≥ 2 year follow up respectively) following gastric banding, 79.74% (81.44 and 77.46%) following gastropasty, 80.28% (81.60 and 70.90%) following RYGB, and 95.05% (94.0 and 95.85%) following BD/DS.

In addition the authors performed a sub-analysis on 12 studies that included only subjects with diabetes ($n=963$) and reported overall resolution of diabetes in 79.29% (81.81 and 62.08%), and resolution or improvement in 98.91% (98.56 and 100%). It should be noted however that data for ≥ 2 year follow up in studies that recruited only those with diabetes included only 48 subjects (31 who underwent RYGB and 17 who underwent gastric banding). Of those who underwent RYGB, 80.65% remained in remission from diabetes at ≥ 2 years whilst all patients had experienced at least improvement in glycaemic control. Less impressively, only 41% (7/17 subjects) who had undergone gastric banding remained in remission from diabetes at 2 years. Additionally, the definition of resolution or improvement of diabetes, or even the diagnosis of diabetes itself, varied significantly across the included studies. Overt diabetes was generally defined as an HbA1c of > 53 mmol/mol (7%) whilst most international organisations that accept HbA1c as a diagnostic tool currently suggest cut off values of between 45 and 50 mmol/mol, with a lower range reflective of less severe abnormalities in glucose homeostasis. Secondly, resolution of diabetes was confirmed in some studies on the basis of a measured fasting glucose without the requirement of either further testing or perhaps more robust HbA1c assessments. Improvements in diabetes control was also defined biochemically as a reduction of fasting glucose to between 5.5 -6.9 mmol/L irrespective of HbA1c. As the rationale behind glucose lowering in patients with diabetes is to prevent longer term micro and macrovascular complications, and HbA1c correlates best with the risk of these complications irrespective of day to day fluctuations in plasma glucose measurements, this approach may incorrectly attribute improvement to an otherwise unaltered state. The authors acknowledge that only 4.7% of the contributing studies were randomised controlled trials, and the level of evidence was generally poor (1.6% (10/621) studies assessed as contributing class 1 evidence as per CEBM criteria).

Yip and colleagues performed a large meta-analysis including all studies that reported on diabetes outcomes following either gastric bypass or sleeve gastrectomy.[30] Inclusion criteria used to identify suitable studies were the recruitment of patients aged 18 years or over, the presence of type 2 diabetes prior to bariatric surgery, participants undergoing either gastric bypass or sleeve gastrectomy, and the reporting of glycaemic outcomes with specified criteria at comparable time points of assessment. On this basis, 2655 studies were assessed, of which 33 were considered appropriate for inclusion. The majority of these (30, 18 prospective and 12 retrospective) were not randomised, and 31/33 studies compared either gastric bypass or sleeve gastrectomy against a lifestyle/medical therapy “control” group. 2 of the randomised controlled studies compared gastric bypass against sleeve gastrectomy. Reflective of the available literature reporting on diabetes outcomes following bariatric surgery, only 8/35

studies of outcomes following gastric bypass and 1/16 studies of outcomes following sleeve gastrectomy had a duration of follow up of >12 months. Reported definitions of glycaemic outcome required an HbA1c level below a specified threshold in the absence of glucose lowering therapy.

Using this definition, diabetes remission was achieved by 67% and 56% in those who had undergone gastric bypass and sleeve gastrectomy respectively at 3 months, 76% and 68% at 12 months, and 81% and 80% at 36 months. The authors noted that the differing definition of diabetes remission used had a significant effect on reported outcomes; in those participants who had undergone sleeve gastrectomy, collective studies that defined diabetes remission as an HbA1c <6.0% (42 mmol/mol), <6.5% (47 mmol/mol) or <7.0% (53 mmol/mol) reported diabetes remission in 44.0%, 67.8% and 75.8% of participants respectively.

CONCLUSION

Early improvements in glucose homeostasis were noted soon after the first bariatric procedures were performed, and a huge volume of evidence validating this phenomenon has since been published. Whilst the study quality and design has varied considerably, the overall assessment of this literature strongly supports bariatric surgery as valid treatment option for obese persons with type 2 diabetes. Indeed, in well designed randomised controlled trials, bariatric surgery is far superior to conventional lifestyle and medical therapy in terms of achieving improvements in glycaemic status alone. Studies presented in this chapter that included a lifestyle/medical arm illustrate the difficulty in achieving improvements in diabetes control that could constitute remission even in a research setting; when stringent criteria for diabetes remission were applied, on average 10% or less of participants in these arms achieved diabetes remission. These findings are clearly of high importance when considering the relative benefit of bariatric surgery in comparison to other treatment options for the management of type 2 diabetes in obese persons.

The marked study heterogeneity with respect to criteria and severity of type 2 diabetes at recruitment, BMI at baseline, specific bariatric procedure performed (even amongst studies purportedly studying the same bariatric modality), definitions of glycaemic outcomes utilised, and concurrent use of medical/lifestyle therapies, means that an absolute stratification of each bariatric procedure to the relative impact on glycaemic control is not possible. Nonetheless, the suggestion of a trend of increasing benefit on glycaemic control with gastric banding (diabetes remission/control at greater than 12 months follow up, seen in 17-73% of included studies), sleeve gastrectomy (11-85%), gastric bypass (24-93%), and biliopancreatic diversion (30-100%) is in keeping with the increasing weight loss seen respectively with each of these procedures in the published literature. In many respects, the interest lies in the analysis of studies reporting on sleeve gastrectomy and gastric bypass as these two procedures are perhaps more comparable than other bariatric procedures. With one exception (Vidal et al, where 85% diabetes remission rates were seen in both arms), all other studies that included both gastric bypass and sleeve gastrectomy, showed improved rates of diabetes remission in those who had undergone gastric bypass. Indeed, this relationship was preserved when one considers outcomes at each follow up interval with improved diabetes remission rates following gastric bypass at 12 months (42-93% versus 23-85% in those undergoing gastric

bypass and sleeve gastrectomy respectively), 24 months (33 versus 11%, one study reported [12]) and greater than 24 months (38 versus 24%, one study reported [23]). Whether this apparent benefit on glycaemic outcome of gastric bypass against sleeve gastrectomy translates into clinically meaningful improvements remains to be clarified, as significant reductions in body weight alone are seen following either procedure.

Understandably, many physicians treating patients with type 2 diabetes have historically been reluctant to refer these patients for bariatric surgery, given a paucity of published data on longer term outcomes. This is especially true of younger patients, where the expected long lifespan following surgery clearly increases the risk that any longer term consequences of surgery may negatively affect outcomes. The studies presented above go some way to providing reassurance in this respect, and whilst well designed studies assessing the longer term effect of bariatric surgery on glycaemic complications such as nephropathy, retinopathy, cardiovascular disease are needed, longer term effects on glycaemic status alone are clearly impressive when compared with other currently available therapies. Many authors feel that the more pertinent contemporary question is not if bariatric surgery should at the forefront of therapeutic strategies for obese persons with type 2 diabetes, but at how early it should be performed. Inclusion criteria for many publically funded bariatric surgery programmes internationally select on the presence of more rather than fewer obesity or diabetes related complications; increasing evidence as to the long term efficacy and safety of bariatric procedures would surely therefore require that this approach is reassessed.

In summary, whilst the degree of improvement varies across the published literature, in part because of consistent inconsistencies in the definitions used, the evidence thus far supports a significant and clinically important durable effect of bariatric surgery on glycaemic status. Control groups included in these studies highlight the difficulty in achieving these results without bariatric surgery, even in the context of intensive research based lifestyle and medical interventions. Further research is required to assess the longterm impact on other diabetes related outcomes, but, as per recent statements from the International diabetes federation (IDF), bariatric surgery should now be considered early in the management of obese persons with type 2 diabetes. ABSTRACT

Morbidly obese patients are already at high risk for cardiovascular and respiratory functional overload related to varying degrees of metabolic syndrome. Most of patients request for bariatric surgery in an early stage of the disease, therefore low rates of mortality and morbidity are the standard. Even that, perioperative complications are related to previous comorbidity, age, body mass index and type of bariatric surgery. Restrictive procedures are not expected to have mortality, but all complication rates are 3.2%, and readmission rate is 4.3%. For gastric bypass procedures, the complication rate is 16%, the readmission rate of 6.6% and mortality around 0.4%, which account intra operatively in 0.18%. of patients. Consequently, anesthetic management of morbid obese patients is a challenge, even to an experienced anesthesiologist and to do that effectively, these key points have to be considered:

ABBREVIATIONS

BMI	body mass index
OSA	obstructive sleep apnea
TOFr	the train of four stimulus ratio

1. SAFETY IN AIRWAY PROCUREMENT AT ANESTHESIA INDUCTION

In order to facilitate oxygenation and the airway management, patients are placed in semi-sitting position and oxygen is administered to increase tolerance to apnea.

Because neck fat accumulation, difficult tracheal intubation is present in around 10% of patients.

Awake intubation is indicated when a limited mandible advancement is associated to a short thyromental distance [< 6 cm] and a Mallampati class 2/3/4. This conservative approach try to reduce the “can ventilate and can't intubate” crisis, noticed in a range of 0.3-1.2% of patients.

Awake tracheal intubation with videolaryngoscope is a good alternative to fiber optical intubation. The introduction of sugammadex, which is able to quickly reverse a neuromuscular blockade of any depth and ensure complete recovery of pharyngeal muscles, have displaced the use of succinylcholine for the patients in whom a general anesthesia induction is planned.

2. MAINTENANCE OF ANESTHESIA DURING LAPAROSCOPIC PROCEDURES

In laparoscopic surgery a deep neuromuscular blockade facilitates ventilation and ensures an adequate surgical field. From a clinical point of view, although neuromuscular monitoring is not widely used, it is therefore advisable. In relation to ventilation strategies during surgery, there is some evidence that recruitment maneuvers added to positive expiratory pressure improved intraoperative oxygenation; but, there is no evidence of any difference between modes of ventilation. Both, desflurane and sevoflurane are suitable for maintenance of anesthesia, and patients are fully awake in a few minutes after switched off the vaporizer. Moreover, both reversal of neuromuscular blockade and consciousness are necessary for a safe tracheal extubation at the end of anesthesia.

Neuromuscular monitoring of depth is necessary in the morbidly obese to dose neuromuscular blockade antagonist to prevent residual paralysis, which affects genioglossus muscle activity during deep inspiration, causing retroglossal and retropalatal narrowing. These effects are particularly dangerous in morbidly obese patients because of the possible presence of obstructive sleep apnea syndrome.

The dose of sugammadex must be sufficient to affect the gradient between the peripheral and central compartments and more is required when repeated doses or continuous infusion of rocuronium.

3. POSTOPERATIVE MANAGEMENT

Even if most patients are managed in ward, close supervision during 4-6 hour after surgery is mandatory. Postoperative continuous mechanical ventilation is necessary in less than 1% of patients; at risk are those affected by more severe hypoventilation syndrome or

when hemorrhage or leaks are present. On the contrary, obstruction of upper airway and the limited functional respiratory capacity in morbid obese patients are common and facilitate hypoxemic episodes after bariatric surgery. To prevent it, reintroduction of continuous positive airway pressure is crucial. Also, a multimodal analgesia without opioid is preferable. Sitting bed patient position and early mobilization helps to fast-track process that will take 2-4 days.

1. Anesthesia Consideration and Management for Bariatric Surgery

The prevalence of morbid obesity has multiplied in the last fifteen years, and it has been associated with higher mortality in comparison with non obese population. Morbidly obese patients are at high risk of cardiovascular and respiratory functional overload related to varying degrees of metabolic syndrome. Most of the patients need bariatric surgery in an early stage of the disease to ensure low rates of mortality and morbidity are the standard. Because of that, a composite measure, which will involve combining serious complications, reoperations, and readmissions, is advisable to predict performance of the surgery. It is important to note that cardiovascular disorders are no longer a contraindication of surgery, and therefore, major postoperative complication and mortality can occur more frequently as morbid obese patient are accepted for any type of surgery.

Perioperative complications are related to the type of bariatric surgery. Restrictive procedures are not expected to have mortality, but all complication rates are 3.2%, and readmission rate is 4.3%. [1] For gastric bypass procedures, the complication rate is 16%, the readmission rate of 6.6% and mortality around 0.4%, which account intra operatively in 0.18% of patients. [1] Sleeve gastrectomy is performed in those high risk patients as an intermediate stage to definitive bypass procedure. Risk stratification predictors are: age, male sex, body mass index (BMI) and comorbidities [diabetes, obesity hypoventilation syndrome and heart disease]. [2-4] Adverse anesthesia intraoperative events [multiple tracheal intubation attempts, sustained dysrhythmia and hypotension and hypercarbia] occurred in 0.9% of the patients. [3].

The whole bariatric population should be screened for obstructive sleep apnea (OSA) through the application of the Epworth sleepiness scale, Stop-band score or a clinical history of nocturnal snoring, morning headache or a large neck circumference, and if some of them are positive, a polysomnography study is mandatory as well as arterial blood gases for those patients affected by hypoventilation syndrome. Smoking cessation and pretreatment with non invasive positive airway pressure ventilation facilitate optimization previous to surgery. The patients with severe hypertension [those on two or more antihypertensive drugs], or history of acute heart disease should undergo cardiovascular evaluation from time to time, and a special attention has to be paid to those super obese patients ($\text{BMI} > 70 \text{ kg.m}^{-1}$). Anesthetic treatment of morbid obese patients is a challenge, even to an experienced anesthesiologist, and to do that effectively some intraoperative key points have to be considered.

1.1. Safety in Airway Procurement at Anesthesia Induction

In order to facilitate oxygenation and the airway management, patients are placed in semi-sitting position and oxygen is administered to them to increase tolerance to apnea.

Because of neck fat accumulation, difficult tracheal intubation is present in around 10% of patients. [5-7]. For obese patients in ramped position, Airtraq™ have a faster tracheal intubation than the Macintosh laryngoscope. [8] It is a general opinion that, awake intubation should be indicated when any element of the triple airway maneuver [mandible advancement, neck extension, and mouth opening] is limited in patients with severe OSA. From our experience, [9] awake intubation is indicated when a limited mandible advancement is associated with a short thyromental distance (<6cm) and a Mallampati class 2/3/4. This conservative approach tries to reduce the “can ventilate and can't intubate” crisis, noticed in a range of 0.3-1.2% in our series of patients. [9] Awake tracheal intubation with videolaryngoscope is a good alternative to fiber optical intubation [10-15]. The introduction of sugammadex, which is able to reverse quickly a neuromuscular blockade of any depth and ensure complete recovery of pharyngeal muscles [16], has displaced the use of succinylcholine for the rest of patients in whom a general anesthesia induction is planned. The outcome of that is a better oxygenation provided by rocuronium in comparison with succinylcholine [17] and a quicker recovery of spontaneous ventilation with rocuronium when high dose of both drugs are used. [18]. In a case report, the administration of sugammadex in a 'can't ventilate' scenario allowed return of spontaneous breathing before the development of hypoxia [19].

It is important to say that the reversal of neuromuscular blockade is not enough to obtain adequate ventilation, which also requires that the patient regain consciousness in order to avoid airway collapse caused by hypnotic drugs. [20]

The dose of propofol for anesthesia induction depends on the weight of the patient, consequently, some adjust to a large dose has to be made if ideal body weight is used to calculate the dose. On the contrary, neuromuscular blocker drugs can be dose by using ideal body weight. However, a rapid sequence induction is advisable for morbid obese patients.

1.2. Maintenance of Anesthesia during Laparoscopic Procedures

It was found that obesity caused a statistically significant increase in respiratory resistance and an increase in inspiratory pressure and a decrease in dynamic respiratory compliance when mechanical ventilation was started in laparoscopic surgery. In non obese patients, a definite plateau in the total exhaled carbon dioxide per minute was observed within 20 minutes from the start of pneumoperitoneum; on the contrary, the total exhaled carbon dioxide per minute increases during the whole surgery in the morbidly obese patients. [21] After disinflation, the total exhaled carbon dioxide per minute returned more rapidly to the baseline values in the non obese patients. [21]

In relation to ventilation strategies during surgery, there is some evidence that recruitment maneuvers added to positive expiratory pressure improves intraoperative oxygenation without changes in blood pressure; but, there is no evidence of any difference between pressure controlled ventilation and volume controlled ventilation. [22] A deep neuromuscular blockade facilitates ventilation and ensures an adequate surgical field facilitating the surgical procedure. From a clinical point of view, although neuromuscular monitoring is not widely used, it is therefore advisable to use it in all patients, being the train of four stimulus ratio [TOFr] at abductor pollicis the recommended monitor.

End-tidal of sevoflurane leading to a BIS value below 50 in 50% of the morbid obese patient has been observed in 1.6%, higher than that previously reported in non obese patients,

0.97%, and less than that reported in children, 2.8%. [23]. Both, desflurane and sevoflurane are suitable for maintenance of anesthesia, although, desflurane increased intestinal motility and decreased surgeon satisfaction compared with sevoflurane. [24].

Both, reversal of neuromuscular blockade and consciousness are necessary for a safe tracheal extubation at the end of anesthesia. On the basis of the awareness of residual neuromuscular blockade and its clinical implications, drug used during anesthesia should be considered in the morbidity risk analysis.

Neuromuscular monitoring of depth is necessary in the morbidly obese patients to dose neuromuscular blockade antagonist so as to prevent residual paralysis, that affects genioglossus muscle activity during deep inspiration, and causes retroglossal and retropalatal narrowing, with airway flow limitation; [25-27] changes also occur in swallowing as well as in inspiratory capacity and ventilatory response to hypoxia, which are reduced. [28, 29] These effects are particularly dangerous in morbidly obese patients because of the possible presence of obstructive sleep apnea syndrome. [30] Also at higher risk of upper airway collapse during the perioperative period, these patients should be fully awake and the neuromuscular blockade fully reversed before tracheal extubation is attempted. [31]

In contrast to anticholinesteric agent, sugammadex is able to reverse intense neuromuscular blockade, in a first step, and captures free rocuronium, leading to release of rocuronium from cell receptors. Even though the pharmacokinetic profile of sugammadex is affected by age and renal function, quick reversal (<2 minutes) occurs in lean patients after a sugammadex dose of 2 mg.kg⁻¹ [moderate blockade] or 4 mg.kg⁻¹ (deep blockade), either with propofol or sevoflurane for anesthesia maintenance. [32] The dose of sugammadex must be sufficient to affect the gradient between the peripheral and central compartments and more is required with repeated doses or continuous infusion of rocuronium. Overdoses will which result from using real body weight in morbidly obese patients in the standard calculations will be costly and ineffective in a high number of patients given the ceiling effect. Moreover, the safety and efficacy of sugammadex dose based on the ideal body weight has been questioned.

Table 1. Dose of Sugammadex. Summary of data reported in bariatric surgery

	Dose mg/kg Real body weight	Time to TOF 0.9 [sc]	Time to tracheal extubation [sc]
Moderate blockade [T2]			
Standard Patients	2 mg/Kg	90 sc	
Obese Patient			
Van Lancker [33]	1.34 mg/kg	120 sc	255 sc
Van Lancker [33]	2 mg/Kg	128 sc	326 sc
Gaszynski [34]	1.29 mg/Kg	167 sc (265 sc)	-
Llaurado [35]	1.23 mg/Kg	113 sc (300 sc)	220 sc
Sanfilippo [36]	1.075 mg/Kg	151 ± 44 sc	
Sanfilippo [36]	2 mg/Kg	121 ± 21 sc	
Deep Blockade			
Standard Patient	4 mg/kg	90 sc	
Obese Patient			
Llaurado [35]	2.3 mg/Kg	167 sc (460 sc)	586 sc

Many morbid obese patients on sugammadex have different types of responses or reactions depending on the type of anesthesia, the total dose of neuromuscular blockade drug and time from the last dose of rocuronium.

Table 1 represent a summary of sugammadex dose studies. [33-36] We can identify patients who are likely to exhibit more variability of response by monitoring neuromuscular blockade. In one study, [37] the risk of TOF ratio <0.9 in tracheal extubation after sugammadex remains as high as 9.4% in a clinical setting in which neuromuscular monitoring was not used.

Likewise, the percentage of patients requiring an additional dose of sugammadex tended to be larger in the deep neuromuscular blockade at the end of procedure. [35] It is also interesting that time until extubation was much longer in patients with deep blockades. [35] The short interval between the administration of the last doses of rocuronium and sugammadex were associated with a higher incidence of postoperative residual weakness. [37] Again, some case reports advice on resistance to sugammadex. [38-39].

1.3. Postoperative Management

Even if most patients are treated in ward, in a setting of fast-track surgery [40] close supervision from 4-6 hour after surgery is mandatory, because morbid obese patients carry significantly increased risk of extubation failure and are frequently associated with difficult airway management. Extubation failure is caused by loss of upper airway patency; edema, soft tissue collapse, and laryngospasm which are among the most frequent mechanisms of upper airway obstruction.[41] Anesthesia induced atelectasis occurs in nearly all anesthetized patients; even if reversible after bariatric surgery, and hypoventilation syndrome determine respiratory complications in the postoperative period. [42] The reasons for abnormalities in regional ventilation produced during anesthesia and surgery are: hypoventilation due to pain or residual anesthetics, lung edema due to fluid overload and exacerbation of chronic obstructive pulmonary disease. [43] A clinically relevant fade in forced vital capacity is produced as a consequence of residual neuromuscular blockade. [44] Therefore, strategies to prevent respiratory complication or improve ventilation such as multimodal analgesia without opioid, sitting bed patient position and early mobilization, have to be implemented to help fast-track process that will take 2-4 days. [45]

Postoperative continuous mechanical ventilation is necessary in less than 1% of the patients; at risk are those affected by more severe hypoventilation syndrome or those with hemorrhage or leaks. Obstruction of upper airway and the limited functional respiratory capacity in morbid obese patients are the consequences of hypoxemic episodes after bariatric surgery. [46] To prevent it, reintroduction of continuous positive airway pressure is crucial, as well as adequate reversal of neuromuscular blockade. [47, 48] Fewer episodes of postoperative oxygen desaturation [46] and less likely associated with X-ray results are consistent with postoperative complete reversal of neuromuscular blockade. [47, 48]

2. New Insights in Morbid Obese Patients' Management

A recent systematic review of medical journals concluded that there is no adequate information to make strong recommendations regarding appropriate selection of the obese

patients scheduled for ambulatory surgery. However, the super obese patient (BMI>50 kg/ m) do present an increased risk for perioperative complications. [49] Patients affected by obstructive sleep apnea may be accepted for ambulatory surgery if they are able to use a continuous positive airway pressure device in the postoperative period and pain can be managed without opioid drugs. [50] A recent report indicates safety of performance of bariatric restrictive procedures in ambulatory regimen, 0.8 % of patients were transferred from the Ambulatory centre to a hospital and 3.6% of patients were readmitted within 30 days. [51] By using laryngeal mask instead of tracheal intubation, the requirements for neuromuscular blockade drugs were reduced and time to discharge the patients from both the postanesthesia care unit and the hospital also was reduced; [52] however, in two patients laryngeal mask had to be removed because of initial placement failed and in one patient a laryngospasm occurred after removal, which represent 8% of the failures.

For those patients with recurrent episodes of pulmonary thrombi embolism or with the contraindication of prophylaxis, the use of vena cava filters will remain controversial, even though its use continues to rise. [53] Thrombosis of vena cava related to filters is uncommon, but it may be present in at least 3% of the patients.

ABSTRACT

Worldwide, the prevalence of obesity continues to rise. Attempts at modification of diet and lifestyle often fail to prevent the medical complications of obesity. Bariatric surgery is being increasingly utilized for treatment of obesity. Despite being a gold standard therapy for management of medically-complicated obesity, bariatric surgery has been associated with multiple complications including nutritional deficiencies, bloating, and dyspepsia. Ongoing clinical research has shown that bariatric surgery can lead to postoperative small intestinal bacterial overgrowth with its related nutritional deficiencies. Bacterial overgrowth may result from alteration of the host defense mechanisms, including loss of gastric acid or diminished exposure to bile acids, and altered upper gastrointestinal motility. Other co-morbid disorders, including diabetes mellitus, chronic narcotic use, use of proton pump inhibitors and antidepressants appear to play a role in the development of bacterial overgrowth. Although microbial investigation of jejunal aspirates is the gold standard for detecting bacterial overgrowth, glucose-hydrogen breath testing is increasingly becoming the test of choice for this diagnosis. The treatment for bacterial overgrowth can be very challenging and can include treatment of the underlying disease, correction of vitamin deficiencies, and discontinuation of motility-altering medications. Antibiotics are effective, but only a few studies concerning choice of and duration of antibiotic therapy exist. Herein, we describe the potential mechanisms for the development of small intestinal bacterial overgrowth,

the effects of bacterial overgrowth on nutrients, the methods of diagnosis of bacterial overgrowth, and treatment options for this disorder.

INTRODUCTION

Microbiota of the Alimentary Tract

Small intestinal bacterial overgrowth (SIBO) results in a malabsorption syndrome due to an increase in and/or alteration of microorganisms within the upper gastrointestinal tract. It is a condition in which there is an expansion of bacteria in the small intestine resulting in excessive fermentation and malabsorption, which can significantly impair an individual's quality of life.

This is not a new surgical disorder. In a 1955 publication, Dr. James Halsted commented that: "intestinal anastomosis leading to stasis of intestinal contents, with overgrowth of bacteria, may cause vitamin B12 deficiency through bacterial interference" [1]. Early work demonstrated that concentrations of the bacterial flora in the gastrointestinal tract normally vary along the length of the gastrointestinal tract [2].

In human physiology, bacterial fermentation is limited to the distal gut as well as to the large intestine. The duodenum and jejunum are relatively sterile. Therefore, colonization of bacteria in the upper gut is abnormal. In this syndrome of SIBO, the flora of the proximal small intestine begin to resemble the flora of a healthy subject's colon, developing high concentrations of anaerobic bacteria. In patients who have undergone bariatric surgery, it would be reasonable to expect that the altered upper gut flora would resemble species present in mouth flora since individuals are frequently swallowing fluids (including saliva). This assumption however has not been confirmed by studies involving subjects after bariatric surgery.

Bacterial concentrations in the upper small intestine typically are low due to effects of gastric acid, gastric emptying, and normal small intestinal motility. The concentration of bacteria in the cecum is usually 10^{10-12} colony forming unit (cfu)/ml; in the ileum bacterial concentrations drop to 10^{5-8} cfu/ml, and in the jejunum and the duodenum bacterial concentrations further drop to 10^{0-4} cfu/ml [3-5]. Therefore, for fermentation to occur, food must normally reach the distal gut anaerobic bacteria. Expansion of bacterial populations in the upper gut can be blocked by several defense mechanisms, including the intestinal immune system, gastric acid, gastric emptying, pancreatic enzymes, intraluminal bile, and small intestinal motility (see Table 1). If any of these mechanisms fail, SIBO could then develop [6]. In addition, in the small intestine, the cleansing action of peristalsis especially the interdigestive migrating motor complex (termed MMCs) is important for the propulsion of bacteria into the colon [7]. Therefore, conditions that result in dysmotility of the small intestine could lead to upper gut bacterial overgrowth.

Predisposing Factors

The etiologies of SIBO are complex and are summarized in Table 2. The origin of SIBO includes clinical disorders and anatomical abnormalities such as bariatric surgery, partial gastrectomy with Billroth II reconstruction, small intestinal diverticulosis, small intestinal stricture (due to Crohn's disease, radiation enteritis, or focal segmental ischemia), fistulae, or previous resection of the ileocecal valve. Other predisposing factors involve disorders of protective antibacterial mechanisms including the presence of pancreatic insufficiency or achlorhydria [7]. Motility disorders that can induce SIBO include scleroderma, diabetes mellitus with autonomic neuropathy, or chronic idiopathic intestinal pseudo-obstruction. Other disorders associated with SIBO include celiac disease, chronic pancreatitis, and radiation enteritis [7-9].

Table 2. Clinical conditions and the development of small intestinal bacterial overgrowth

Anatomical Alteration
Bariatric Surgery
Small Intestinal Diverticulosis
Intestinal Stricture (Benign, Malignant, Radiation-Induced or Crohn's disease)
Fistula (Gastrocolic or Jejunoileocolic; Crohn's disease)
Resection of Ileocecal Valve
Altered Gastric Acid Production
Post-Surgical Gastrectomy or Vagotomy
Chronic <i>Helicobacter pylori</i> gastritis
Proton Pump Inhibitor
Dysmotility Disorders
Gut Autonomic Neuropathy (Diabetes Mellitus)
Scleroderma
Motility-Altering Medications (Narcotics, Anti-Depressants, or Calcium-Channel Antagonists)
Medical Disorders
Immunodeficiency Disorders
Celiac Disease
Chronic Pancreatitis

There are reports in the literature that use of chronic narcotics, proton pump inhibitors, and antidepressants could increase the likelihood of developing SIBO, but these factors have not been extensively studied [10].

We have evaluated the association between medication use and SIBO in patients after Roux-en-Y gastric bypass [11]. In a retrospective study that included 206 patients who underwent Roux-en-Y gastric bypass at our institution from 1999-2007, all patients were required to take a daily multivitamin with minerals. A serum folate level above the upper limit of normal was considered to be elevated and therefore consistent with a diagnosis of SIBO [12-13]. There were 115 patients (97 females and 18 males; average age: 46 years-old; average BMI: 53 kg/m²) who had serum folate levels measured. Medication lists for these patients after gastric bypass were reviewed, and short-term narcotic use in the immediate post-operative period was excluded. There were 58 patients with chronic narcotic use of whom 51 had elevated serum folate levels; in a control group of 32 patients who received no motility-altering medication, only 10 patients had elevated serum folate levels (Chi-squared 2x2: $p < .0001$). This result supported the strong relationship between chronic narcotic usage and SIBO. Among the 25 remaining patients, 13 of 13 patients (100%) who were receiving an anti-depressant medication had elevated serum folate levels, 8 of 9 patients (89%) who were receiving a proton pump inhibitor had elevated serum folate levels, and 2 of 3 patients (67%) who were receiving a calcium channel antagonist had elevated serum folate levels. These results support the concern that patients after bariatric surgery may be at risk for development of SIBO during concomitant intake of narcotics, proton pump inhibitors, anti-depressants, or calcium-channel antagonists.

SIBO has been identified by clinical evidence and abnormal glucose-breath tests in patients who have undergone Roux-en-Y gastric bypass (as discussed above), vertical sleeve gastrectomy, and adjustable gastric banding.

It has been suggested that inadequate small intestinal motility may result in the presence of residual food particles or residue in the small intestine, a potential culture media for bacteria. Specifically, a reduction in the frequency or occurrence of interdigestive (fasting) migrating motor complexes (MMC) could result in the development of small bowel bacterial overgrowth. However, a study from the Mayo Clinic (Rochester, MN) reported however significant increases in the frequency of phase III MMCs in individuals who had undergone partial gastrectomy with either Billroth II reconstruction or Roux-en-Y reconstruction [14].

By contrast, investigators at the University of Copenhagen (Denmark) studied 17 individuals after Roux-en-Y gastric bypass and compared their results to 9 controls [15]. Small intestinal transit was examined using gamma camera images in individuals receiving mixed isotope solid-liquid meals. The passage of solid isotope, but not liquid isotope, was significantly prolonged through the small intestine in individuals who had undergone Roux-en-Y gastric bypass. Slowed passage of solids through the small intestine could be an important factor promoting the overgrowth of upper gut bacteria.

Advanced age may be an independent risk factor for SIBO [16]. However, the incidence of SIBO may be underestimated, since many of these patients are asymptomatic. The underlying mechanism has been proposed to be due to age-related dysmotility or achlorhydria (possibly caused by atrophic gastritis induced by chronic gastric *Helicobacter pylori* infection). Further studies are needed to determine the actual incidence of SIBO in this population.

Mechanisms of Malabsorption

Proposed mechanisms of malabsorption in individuals with SIBO are summarized in Table 3. Bacteria in the small intestine can interrupt the metabolism and absorption of many bioactive compounds including monosaccharides, lipids, proteins and vitamins [1, 13, 17, 18].

Table 3. Proposed mechanisms of malabsorption induced by small intestinal bacterial overgrowth

Bacterial Deconjugation of Bile Salts
Reduced Brush Border Disaccharidases
Carbohydrate Fermentation by Bacteria
Formation of Short-Chain Organic Acids
Utilization of Protein by Bacteria
Altered Gut Permeability
Utilization of Vitamins by Bacteria
Interference with the Cobalamin-Intrinsic Factor Complex

Fat malabsorption in SIBO has been proposed to result from bacterial deconjugation of bile salts in the proximal gut. Conjugated bile salts are required for micelle formation (containing lipids and fat-soluble vitamins A, D, E and K) prior to micelle absorption in the terminal ileum. However, in individuals with SIBO, bacteria in the small intestine deconjugate bile salts forming free bile acids, which can interfere with formation of mixed micelles. Furthermore, deconjugated bile acids formed by bacterial activity may induce mucosal damage, and thus contribute to patchy submucosal lesions identified in individuals with SIBO.

Although malabsorption of lipophilic vitamins (vitamins A, D, E, and K) may also occur as a result of altered micelle absorption, vitamin K levels are generally normal in patients with SIBO due to the production of vitamin K by luminal bacteria [17-19].

Carbohydrate malabsorption is also common in SIBO. This phenomenon has been proposed to be the result of reduced brush border disaccharidase levels (due to digestion by bacterial proteases) as well as carbohydrate fermentation by the bacteria, itself. In addition, small intestinal and colonic bacteria can metabolize these malabsorbed carbohydrates to form short-chain organic acids, which leads to increased osmolarity of the intestinal fluid and thus results in diarrhea [17, 20].

Protein malabsorption has been proposed to be the consequence of utilization of protein by the bacteria. Another proposed mechanism may be the enterocyte injury which alters the gut permeability leading to the development of a protein-losing enteropathy [21].

The postoperative development of vitamin B12 deficiency induced by SIBO has a complex pathophysiology. In a healthy proximal small intestine, intrinsic factor normally binds to vitamin B12. This complex will facilitate cobalamin absorption in the distal ileum. In the presence of SIBO, the colonized bacteria including anaerobes and facultative gram-negative aerobes utilize or consume vitamin B12 making it less available for absorption. In SIBO, bacteria can interfere with the formation of the cobalamin-intrinsic factor complex. Interestingly, enteric bacteria do biosynthesize cobalamin. However, this cobalamin is not available for absorption by the host as it is retained by the bacteria [3, 17, 22].

Effects of Small Intestinal Bacterial Overgrowth on Nutrition

Small intestinal bacterial overgrowth may include a catabolic process that could lower serum albumin levels. The preoperative prevalence of hypoalbuminemia in patients seeking bariatric surgery is reported to be 1.1% [23]. Clinicians in Brazil have reported two patients who developed hypoalbuminemia after Roux-en-Y gastric bypass [24]. Hydrogen breath testing supported a diagnosis of bacterial overgrowth. Each patient was treated with oral ciprofloxacin for two weeks and one patient in addition received a two week course of oral tetracycline. One patient had a rise in serum albumin from 2.4 g/dl pre-treatment to 3.3 g/dl post-treatment, while in the second patient, the serum albumin pre-treatment was 2.3 g/dl but the post-treatment level was only 2.7 g/dl (normal range is 3.5 to 5.0 g/dl).

Upon examination of patients who underwent Roux-en-Y gastric bypass surgery at our institution from 1999-2007, we identified 115 individuals who had both serum folate and serum albumin levels obtained [25]. A serum folate level above the upper limit of normal was considered to be an indirect measure of small intestinal bacterial overgrowth [12, 13], and a serum albumin level below the lower limit of normal was considered to be low. In this study, 42 patients with an abnormal glucose-hydrogen breath test, consistent with SIBO, were treated with oral antibiotics. There was no relationship identified between SIBO and low serum albumin levels (Chi-squared 2x2: $p=0.8$). Among 42 patients with abnormal glucose-hydrogen breath test, 14 patients (33%) had low serum albumin levels and 42% of these patients achieved normal serum albumin levels after antibiotic treatment for SIBO (see Figure 1). Thus, there was no evidence that SIBO induced hypoalbuminemia; treatment of SIBO did not improve serum albumin levels in the majority of patients after Roux-en-Y gastric bypass.

In an attempt to suppress the development of SIBO, Woodard and associates followed 44 patients after Roux-en-Y gastric bypass who were randomized to receive either a control (placebo) or 2.4 billion *Lactobacillus* species daily [26]. At 6 months, individuals who received daily *Lactobacillus* had reduced breath hydrogen levels, supporting suppression of upper gut bacterial overgrowth. However, there were no differences in weight loss when comparing the two groups of patients at 6 months. It was noted that gastrointestinal quality of life surveys had improved in both groups, supporting the importance of gastric bypass surgery in improving patients' quality of life.

In examination of the effect of SIBO on vitamin B12, SIBO classically causes megaloblastic anemia [1]. Cobalamin (vitamin B12) deficiency can occur as a result of utilization of the vitamin by the bacteria before it can be absorbed. This deficiency is improved after antibiotic administration, but cannot be corrected by addition of intrinsic factor.

We have reported the effect of SIBO on vitamin B1 (thiamine) levels after Roux-en-Y gastric bypass [13]. There was a significant relationship between the presence of SIBO and whole blood thiamine diphosphate levels that were below the lower limit of normal.

Twenty one patients were also evaluated who had thiamine diphosphate levels below the lower limit of normal and abnormal glucose-hydrogen breath tests, consistent with SIBO [13]. Fifteen patients received oral thiamine supplements, but repeat whole blood thiamine levels remained low in all 15. Nine of these patients then received oral antibiotic therapy. Determination of repeat thiamine levels revealed that all 9 patients had normalized their whole blood thiamine levels. These results support the hypothesis that SIBO induces thiamine deficiency after gastric bypass surgery in obese patients. Patients after gastric bypass surgery

who develop thiamine deficiency may require antibiotic treatment of SIBO in order to normalize their whole blood thiamine levels.

MANAGEMENT

Clinical Features

As discussed above, SIBO is generally considered to be a malabsorption disorder. The clinical consequences of SIBO are similar regardless of the underlying predisposing factors (see Table 4). Patients with SIBO may be asymptomatic or may have symptoms that resemble the irritable bowel syndrome, including diarrhea, abdominal bloating, abdominal cramps, or flatulence. These symptoms are usually followed by the development of malabsorption. In patients with short bowel syndrome, inflammatory bowel diseases, scleroderma, radiation enteritis or diabetes, it may be difficult to determine whether the symptoms are due to the primary disease, or SIBO itself [3].

Many patients with SIBO fulfill Rome I criteria for a clinical diagnosis of irritable bowel syndrome, because the symptoms of SIBO and irritable bowel syndrome overlap to a large degree. Pimentel et al. [3] have reported that among 202 patients meeting Rome I criteria for IBS, 78% had abnormal breath tests, supporting the presence of SIBO. In their reports, successful eradication of SIBO after antibiotic treatment was associated with significant relief of abdominal symptoms [27].

One of the late features of SIBO is development of anemia. It is usually due to vitamin B12 deficiency, which results in macrocytic and megaloblastic anemia. In prolonged cases of malabsorption, cobalamin deficiency can lead to subacute combined degeneration of the spinal cord and/or peripheral neuropathy. In other severe cases, symptoms such as night blindness (nyctalopia) due to vitamin A deficiency, osteomalacia due to vitamin D deficiency, or vitamin E deficiency syndromes (retinopathy, anemia, ataxia, myopathy, or dysarthria) can occur. Protein malabsorption in SIBO can lead to hypoalbuminemia, which can induce peripheral edema [3].

Nyctalopia
Osteomalacia
Peripheral Edema

Diagnosis

A patient with symptoms of diarrhea, abdominal bloating/pain, or steathorrhea with a coexisting predisposition to SIBO should prompt the clinician to consider testing for small intestinal bacterial overgrowth, especially if there has been no response to empiric treatment. The “Gold Standard” for the diagnosis of a SIBO is a quantitative microbial investigation of a jejunal aspiration [6, 28]. However, this test has fallen out of favor since it has major limitations. First, in order for this quantitative test to be diagnostic, a duodenal aspirate must be obtained and then should be immediately cultured in order to identify the presence of at least 10^6 cfu/mL [29]. Second, the distribution of bacterial overgrowth might be restricted to one particular area of intestine, which may not be within the reach of a gastroscope. Since a gastroscope reaches only the upper portion of small intestine, there could be potentially high false-negative rate when using this approach for the diagnosis of SIBO [3, 30]. Since this quantitative test is invasive, time-consuming, and may be altered by contamination, breath tests such as the xylose breath test and the hydrogen breath test have been developed.

However, there is presently no general agreement as to which test is superior for the diagnosis of SIBO. ^{14}C -cholyglycine or bile acid breath test was the first encouraging breath test for the diagnosis of SIBO [31]. The test was based on the deconjugation of the bile salt by small bowel bacteria, before reaching colonic bacteria. However, it was shown that the test had a high false-negative rate of 30% to 40% with only moderate sensitivity. In addition, there was a concern of falsely positive test results in patients with ileal resection, since the unabsorbed bile salt would reach the colonic bacteria and would be deconjugated [21, 32]. With the development of newer tests, the bile acid test has fallen out of favor.

The ^{14}C -D-xylose breath test is another test with higher sensitivity and specificity. This test depends on the ability of catabolization of xylose by the high concentration of small intestine bacteria with production of $^{14}\text{CO}_2$. One of the advantages of this test is the absorption of both $^{14}\text{CO}_2$ that is produced as well as uncatabolized xylose by the proximal small bowel. These dual measurements could potentially decrease the number of false positive results caused by catabolization of xylose by colonic bacteria [7, 33]. As previously mentioned, studies have shown that the sensitivity and specificity of this test are superior to those of the ^{14}C -bile acid test [34]. Therefore, the ^{14}C -D-xylose test replaced the bile-acid breath test and became a popular test for evaluation of bacterial overgrowth. However, other investigators questioned the accuracy of this test [35], and so additional studies are needed to evaluate the efficacy of this test in patients who have undergone bariatric surgery.

Additional tests have been developed based upon the metabolic activity of upper gut bacteria. As shown in Table 5, metabolic products produced by bacteria include hydrogen, methane, ammonia, d-lactic acid and folate [13]. The pulmonary clearance of methane and hydrogen forms the pathophysiological basis for the glucose-hydrogen breath test. The glucose-hydrogen breath test has become one of the most important diagnostic methods for SIBO, with a reported sensitivity of 62.5% and a specificity of 82% [6, 28]. As shown in Figure 2 in an individual with post-prandial abdominal pain after Roux-en-Y gastric bypass, the diagnosis of a positive or abnormal glucose breath test is supported both by a high fasting breath level of methane as well as by fermentation of glucose to produce hydrogen, which is then measured in the breath.

SERUM ALBUMIN LEVELS BEFORE (CLOSED CIRCLES) AND AFTER (OPEN CIRCLES) ANTIBIOTIC THERAPY

Figure 1. Effect of antibiotic therapy on serum albumin in forty two patients after Roux-en-Y gastric bypass.

Figure 2. Gastric bypass patient with abdominal pain: breath hydrogen/methane levels after 25 grams of oral glucose.

However, there are several limitations when using the glucose-hydrogen breath test, including determination of cut-off points to define a positive test. A positive or abnormal glucose breath test in an individual who has fasted for at least 10 hours is supported by either: i. a fasting breath hydrogen or methane level that is >10 parts per million or, ii. after oral ingestion of 50 grams of glucose, an increase in breath hydrogen or methane of >14 parts per million above the baseline breath hydrogen or methane values. Furthermore, since glucose is almost completely absorbed in the proximal small intestine, this test may not be reliable for the diagnosis of SIBO of the distal small intestine. In patients with rapid transit (oral-cecal transit time of less than 75 minutes), the breath test may not be useful since it could result in false positive results [36]. As another potential downside to this test, after Roux-en-Y gastric bypass, the bypassing of duodenum and proximal jejunum could reduce absorption of glucose by the small intestine, leading to a higher percentage of patients with an abnormal breath test. Nonetheless, this test is one of the most useful methods for the diagnosis of SIBO.

Finally, the lactulose-hydrogen breath test is another test that has been examined in patients with potential SIBO, but its validity has also been questioned. In studies, it has been shown that the lactulose-hydrogen breath test has a sensitivity of 17-68% and specificity of 44-70%; therefore this test may not be useful for the diagnosis of SIBO [5].

Treatment Options

The treatment of SIBO can be complex and multifactorial. The treatment of SIBO essentially should focus on: 1) treatment of the underlying disease; 2) modification of the diet, such as a trial of a lactose-free diet; 3) discontinuation of acid-lowering or motility-altering medications; 4) correction of vitamin deficiencies and nutritional support as indicated; 5) treatment of potential dysmotility disorders; and 6) antibiotic treatment targeting the bacteria that cause SIBO.

Individuals with SIBO may be asymptomatic. However, if symptoms of malabsorption such as diarrhea and bloating occur in the presence of a positive breath test result, the clinician may decide to start antibiotic therapy for SIBO (see Table 6). There have been many studies examining different antibiotics, but no guidelines have been published with regards to the choice of antibiotics or the duration of the treatment for management of recurrent SIBO. This is partly due to the difficulty in acquiring a culture of bacteria from the small intestine, as well as determining its antibiotic susceptibility. Generally, empiric antimicrobial agents are used that have both aerobic and anaerobic coverage. Cycling of antibiotics involves utilization of an antibiotic for 7 to 14 days, with consideration of a repeat course of antibiotic in 1 to 3 months (depending upon the timing for a return of abdominal symptoms). In addition, long-term treatment is not optimal as it might be associated with other problems such as development of antibiotic-associated diarrhea, *Clostridium difficile* colitis, and resistance to antibiotics. Also the recurrence rate of SIBO is high.

In a major meta-analysis of antibiotic treatment of SIBO, Shah and associates [37] identified 1356 articles. As their primary outcome, the authors chose normalization of post-treatment breath testing. Their secondary outcome was post-treatment clinical response. Only 10 studies met inclusion criteria. Among these 10 studies, rifaximin was studied in 8 of the studies. This meta-analysis showed that antibiotics were more effective than placebo, and that the clinical response paralleled the results obtained from breath testing.

Table 6. Antibiotic therapy for small intestinal bacterial overgrowth

ANTIBIOTIC	DOSAGE	TIMING
Metronidazole	250-500 mg	2 to 3 Times Daily
Doxycycline	100 mg	1 to 2 Times Daily
Cefaclor	250 mg	3 Times Daily
Amoxicillin-Clavulanic Acid	250-500 mg/62.5-125 mg	2 to 3 Times Daily
Ciprofloxacin	250-500 mg	Twice Daily
Norfloxacin	400 mg	Twice Daily
Rifaximin	200-550 mg	1 to 2 Times Daily
Trimethoprim-Sulfamethoxazole	160/800 mg	1 or 2 Times Daily
Clindamycin*	150 mg	2 to 4 Times Daily

* High risk of pseudo-membranous colitis.

In older literature, the treatment of choice for SIBO was tetracycline, taken by mouth four times a day, with presumed resolution of symptoms within one week. However, new studies have shown that almost half of the patients with SIBO do not respond to this therapy, probably because tetracycline does not have a direct activity against anaerobic bacteria. Eradication rates with tetracycline were also shown to be as low as 40%.

Metronidazole has also been used for treatment of SIBO, but data are scarce with regards to this antibiotic. Metronidazole does provide coverage against anaerobic bacteria. As a potential risk factor, it has been reported that enzymatic conversion of metronidazole produces an analog of thiamine [38]. It is therefore possible that metronidazole could exacerbate thiamine deficiency induced by bacterial overgrowth in patients who have undergone bariatric surgery.

Other antibiotics such as amoxicillin–clavulanic acid have been used previously for empiric treatment of SIBO due to convenience of dosing [7]. Attar and associates compared the treatment of 10 patients with amoxicillin–clavulanic acid, norfloxacin and *Sacchromyces boulardii*. These authors identified significant improvement of symptoms with both amoxicillin–clavulanic acid (60%) and norfloxacin (90%), but no symptomatic improvement with the use of *Sacchromyces boulardii* [39].

There are additional studies which have evaluated the efficacy of non-absorbable antibiotics, including neomycin and rifaximin, to decrease the potential side effects noted with the use of systemic antibiotics. These studies have shown that rifaximin, which has bactericidal activity directed against both aerobic and anaerobic bacteria, led to the normalization of breath testing and the resolution of symptoms of malabsorption [40]. Rifaximin has also been shown to have a very low toxicity, since only < 0.4% of the drug is absorbed [41]. Neomycin has also been studied in older literature. It did not show significant clinical benefit for the treatment of SIBO, and it had no significant side effects.

Given the limited information with regards to the treatment of SIBO, there is no conclusive data to assist our understanding which antibiotics have the most efficacy. Clinicians should consider the risks of long-term systemic antibiotic therapy, costs, and the likelihood of recurrence of SIBO before choosing antibiotic treatment.

Prokinetic agents have also been evaluated due to their potential benefit for propulsion of bacteria through the small intestine. One study of 5 individuals with SIBO demonstrated a decrease in symptoms of bloating and nausea, and normalization of breath tests after nightly administration of low dose Octreotide [42]. Therefore, this agent could be an important option

in those individuals who do not respond to or are intolerant to systemic antibiotics. However, this study included relatively few subjects. Additional studies are required to address questions of the effects of Octreotide, the duration of treatment with Octreotide, and whether its combination with antibiotic therapy could be beneficial to individuals with SIBO.

Although the primary goal of treatment of SIBO is to control the overgrowth of bacteria in the upper gut, nutritional support is an important component for proper management of patients with SIBO. Some of these patients have vitamin deficiencies and some patients have protein-calorie malnutrition. Therefore, appropriate nutritional supplementation with micronutrients and macronutrients is a crucial component of the treatment of SIBO.

The initial goal for treatment of protein malnutrition is the daily intake of 60 to 80 grams of protein. Multiple sources of liquid protein supplementation are commercially available. Vitamin B12 deficiency can be treated with intramuscular vitamin B12 1000 mcg once monthly. Severe vitamin B12 deficiency is treated with intramuscular vitamin B12 500-1000 mcg once daily for 7 days, then once weekly for 3 weeks, and then once monthly. In patients with control of SIBO by antibiotics, vitamin B12 deficiency may respond to oral vitamin B12 500 to 1000 mcg daily. Vitamin B1 (thiamine) deficiency can be treated with 200 mg intramuscularly once monthly. Severe thiamine deficiency (visual loss, Psychosis, or Wernicke's disease) requires 250 mg of thiamine either intramuscularly or intravenously (infusion over 3 to 4 hours) once daily for a minimum of 3 to 5 days. In patients with control of SIBO by antibiotics, vitamin B1 deficiency may respond to oral vitamin B1 100 to 250 mg twice daily.

CONCLUSION

Small intestinal bacterial overgrowth is a malabsorption syndrome which can lead to significant consequences such as deficiencies of macro- and micro-nutrients. It is commonly associated with other disorders and the use of acid-reducing and motility-altering medications. As the rates of bariatric surgeries rise, the risk of developing of bacterial overgrowth increases. Therefore, clinicians should always consider bacterial overgrowth in their differential as a cause of malabsorption. Due to the high incidence of bacterial overgrowth and the difficulty controlling its associated symptoms, further clinical research is warranted regarding antibiotic therapy for bacterial overgrowth. Since indefinite use of antimicrobials is not ideal therapy, further studies are needed to evaluate alternative therapies for the treatment of small intestinal bacterial overgrowth.

ABSTRACT

Bariatric surgery typically results in health improvements across multiple obesity-related comorbidities, in addition to losses of excess weight. It is commonly believed that weight loss following surgery would improve physical activity (PA) levels as movement becomes less difficult, resulting in increased cardiorespiratory (CR) fitness. Increased physical activity levels post-surgery would help optimize and sustain weight loss and other co-morbidity improvements. However, evaluation of fitness and PA levels after surgery-induced weight loss is a nascent field without consensus about the efficacy of current surgical programs to evoke increased fitness and PA changes. Few studies to date have measured changes in different types of fitness, from musculoskeletal function to cardiorespiratory endurance. Furthermore, the limited available research suggesting significant increases in self-reported physical activity following surgery have used objective PA measures, making interpretation difficult. The goal of this chapter is to review existing literature regarding fitness and PA changes following weight-loss surgery. As part of this goal, we will briefly review some basic tenets of physical fitness related to activity and exercise. We will also relate fitness and PA changes to sustained weight-loss and reduced health risks following surgery. Finally, we will highlight gaps in the literature and suggest specific research topics needed to address these relationships, so that optimal bariatric surgery programs can be designed to maximize improvements in fitness.

GLOSSARY OF TERMS

Physical activity	Bodily movements produced by skeletal muscle that result in an increase in energy expenditure.
Exercise	A form of physical activity that is structured with planned sequences of repetitive body movements with the goal of maintenance or improvements in physical fitness.
Physical fitness	Ability to carry out daily tasks with vigor and alertness, without undue fatigue and with ample energy to enjoy leisure-time pursuits and to meet unforeseen emergencies
Overload	Physical activity and exercise that an individual is unaccustomed to presents a positive stressor to various physiological systems.
Adaptation	Molecular, structural, and mechanical changes in physiological systems so that subsequent stressors are adequately handled by the systems.
Injury	Damage done to various tissues or various physiological systems as a result of physical stress.
Cardiorespiratory fitness	The capability of circulatory and respiratory systems ability to deliver fuel during sustained physical activity and to remove metabolic waste products.
Muscular strength	The amount of external force a muscle or a muscle group can exert.
Muscular endurance	The ability of a muscle or muscle groups to repetitively produce external force without undue fatigue.
Body composition	The measurement of the relative amounts of body fat, lean tissue (i.e., muscle), bone, and other vital organs.
Flexibility	The ability to move a joint about its full range of motion.

INTRODUCTION

In response to rapidly increasing rates of obesity, bariatric weight loss surgeries have increased worldwide, reaching approximately 341,000 procedures in 2011 [1]. Bariatric surgery is a major medical intervention with the primary goals of chronically reducing excess weight loss, decreasing incidence and severity of obesity related co-morbidities, and overall improvement in quality of life. Despite widespread evidence of bariatric surgery effectiveness on excess weight loss and resolution of co-morbidities, the effects of weight loss surgery on overall cardiorespiratory fitness and physical activity levels (two critical components of overall health) have yet to be defined.

Increased physical activity is associated with reduced incidences of chronic disease and all-cause mortality [2-4]. Physical activity generally improves overall physical fitness, including its underlying components, including cardiorespiratory, muscular, and metabolic fitness, though specific benefits will vary based on the type and amount of activities done.

While the main goal of weight loss surgery is the reduction of excess weight, improvements in other lifestyle choices (such as physical activity levels) are essential to overall improvements in quality of life [5]. Despite this, very little research is available regarding post-operative improvements in physical fitness or the various components that make up overall physical fitness [6]. A key remaining question is the identification of independent and interactive effects of surgery and weight loss on cardiorespiratory fitness? Another question is whether spontaneous physical activity increases following substantial weight loss. Further investigations regarding changes in physical fitness following surgery are needed for the appropriate exercise prescription for the post-operative populations.

Physical activity plays vital roles in long term excess weight loss and improvements in quality of life following surgery. In previous investigations, those considered to be morbidly obese cite reductions in mobility and physical activity, as a negative impact of their excess weight [7]. This reduced PA can compound the obese state by further reducing energy expenditure. Increased physical activity can positively impact outcomes following weight loss surgery by elevating energy balance both acutely (i.e., during physical activity) and chronically (i.e., elevated resting metabolic rate, maintenance of lean body mass, etc.). However, investigations into the ability of weight loss surgeries to result in improvements in physical activity levels are scarce and inconclusive. Additionally, investigations into optimal strategies for structured/prescribed physical activity recommendations in the weight loss surgery population are lacking.

The purpose of this chapter is to first provide a short primer on fitness and physical activity, followed by a summarization of the literature to date regarding changes in cardiorespiratory fitness and physical activity following bariatric surgery. We will also highlight relationships between enhanced physical activity and fitness and reductions in health risks and obesity related co-morbidities. Finally, we will identify specific areas that warrant further investigation to better understand the relationships between weight loss surgery and improvements in overall health.

EXCESS WEIGHT LOSS EFFICACY FOLLOWING BARIATRIC SURGERY

Most recent estimates indicate that approximately 341,000 metabolic/bariatric surgical procedures occurred worldwide in 2011, of which the Roux-ex-Y gastric bypass (RYGB) accounted for 47%, sleeve gastrectomy (SG) 28%, adjustable gastric banding (AGB) 18%, and biliopancreatic diversion/duodenal switch (BPD/DS) 2.2% of total procedures [1]. These values are estimated from voluntary survey participation of over 50 countries/regions represented in the International Federation for Surgery of Obesity and Metabolic Disorders (IFSO) and may under-represent precise totals.

The most recognizable goal of weight loss surgery is to induce chronic reductions in excess weight, defined as the difference between preoperative weight and the ideal weight and often represented as a percentage ($\% \text{ excess weight loss} = (\text{weight lost} / \text{preoperative excess weight}) * 100$). The most recent meta-analysis of available data (1990 – 2004) indicates that patients lost an average of 61.2% of excess weight following surgery, regardless of the type of procedure performed [8]. Resolution of obesity related comorbidities in patients following surgery were as follows: 76.8% diabetes; 61.7% hypertension; 85.7% sleep apnea

and; hyperlipidemia improved in 70% of patients, regardless of procedure type [8]. There is significant variance in these outcomes based on procedure. We refer readers to Buchwald et al. (2004) for a more complete analysis of the successes of individual procedure types. It is important to point out that most (if not all) of these co-morbidities are also significantly affected by physical activity, meaning that resolution following surgery is affected both by surgery and each patient's physical activity pattern.

While it has widely been shown that bariatric weight loss surgery is successful in acutely reducing excess weight, a growing concern regarding long-term (> 5 yrs.) excess weight reduction and maintenance exists, as well as interest in long-term health improvements [9-11]. A key debate in this area is whether co-morbidity resolution is weight-loss dependent or independent, and to what extent resolution is driven by weight loss itself. As long-term weight loss is augmented by adopting positive lifestyle strategies following surgery, research in fitness and PA changes post-surgery are essential to the success of bariatric surgery programs.

PHYSICAL ACTIVITY, EXERCISE, AND PHYSICAL FITNESS

Before moving on to review the literature on fitness and PA changes following surgery, we feel it is beneficial to provide a short primer on exercise physiology for the current reader. Physical activity and physical fitness have been defined and discussed in detail previously, but here we seek to briefly discuss and summarize these key concepts [12, 13].

Physical fitness is defined as “the ability to carry out daily tasks with vigor and alertness, without undue fatigue and with ample energy to enjoy leisure-time pursuits and to meet unforeseen emergencies” [12]. Evidence overwhelmingly supports a positive relationship between physical fitness levels and health-related risks factors [3]. *Physical activity* is defined as bodily movements produced by skeletal muscle that results in an increase in energy expenditure [12]. Physical activity encompasses many day-to-day activities (such as walking or cooking), as well as participation in planned events such as recreational sports. *Exercise* is a specific form of physical activity that is structured with planned sequences of repetitive body movements with the goal of maintenance or improvements in physical fitness [14].

Physically-active lifestyles delay all-cause mortality, as well as reduce the risk of developing Type 2 diabetes mellitus, coronary heart disease, and multiple forms of cancer [4]. Evidence largely supports a dose-response relationship between the amount of physical activity and health-related outcomes [4, 15], though data regarding the quantities of physical activity required for such benefits is not clear and is likely specific to each outcome. Most large epidemiological studies have found that a minimum of approximately 150 min-wk⁻¹ (~1000 kilocalories-wk⁻¹) is sufficient for health-related benefits [3]. However, few studies have addressed this PA level cutoff, and other lifestyle interventions, in severely obese populations [16].

Physical fitness cannot be described as a singular phenotype, but instead can be divided into five health-related components that can be individually evaluated [3, 17]. Below we discuss the five health-related components of physical fitness, describe how they are clinically evaluated, and note the impact of a physically active lifestyle on each component. For the purposes of this chapter, we will focus most heavily on cardiorespiratory fitness.

Principals of Training and Adaptation

Before discussing the health-related components of physical fitness, it is important to note the basic principles underlying how physical activity and exercise improve physical fitness. The general adaptation syndrome, developed by Dr. Hans Selye, describes three stages of a stress response: alarm and reaction, development of resistance, and finally exhaustion [18]. This model is easily applied to physical activity and exercise to describe how they promote health improvement:

1. **Overload** (alarm and reaction) – physical activity and exercise that an individual is unaccustomed to presents a positive stressor to various physiological systems.
2. **Adaptation** (resistance development) – continual overload applied to a system results in adaptations (i.e., molecular, structural, and mechanical) so that subsequent stressors are adequately handled by the system.
3. **Injury** (exhaustion) – if the overload of the applied stressors from physical activity and exercise is too great or the appropriate adaptations have not occurred, then injuries such as muscle strains, ligament tears, and bone fracturing may result.

Providing adequate overload (without going so far as to evoke a significant injury response) to physiological systems is essential to promotion of positive beneficial adaptations of these systems. Physical activity and exercise have the benefit of being quantifiable and easily adjusted so that the appropriate stressor is achieved and risk of injury reduced. For instance, the intensity of an exercise is easily changed by adjusting the pace (i.e., intensity) at which one walks or runs, while in resistance training the amount of resistance used can be increased or decreased. Another important variable in determining overload is the amount (i.e., dose) of any given physical activity or exercise that is performed. This is easily changed by altering the amount of time spent doing any particular endurance exercise or by decreasing the amount of repetitions during resistance training. Lastly, the frequency at which one participates in any form of physical activity is important to determining the amount of overload that is applied.

A final important principle for physical activity and exercise is specificity. The principle of specificity states that all adaptations will be specific to the applied stressor. Thus, it is important that any exercise or physical activity be planned in accordance with the outcome goal. For instance, if increased muscular strength is desired, resistance-type exercise as opposed to endurance training is indicated. Later in this chapter, we will discuss the recommended amounts, intensities, and frequency of exercise and physical activity to promote health and well-being for specific health-related components following intervention such as surgery.

Cardiorespiratory Fitness

Cardiorespiratory fitness is defined as the capability of circulatory and respiratory systems ability to deliver energy during sustained physical activity and to remove metabolic waste products [12]. Alternatively, it may also be defined as the ability to sustain moderate-to-high intensity exercise for prolonged periods of time [14]. Traditionally, maximal

cardiorespiratory fitness has been determined by a maximal progressive incremental exercise test performed on a cycle ergometer or treadmill, in which the maximal rate of oxygen consumption ($\text{VO}_{2\text{max}}$; $\text{ml O}_2 \cdot \text{kg}^{-1} \text{ body mass} \cdot \text{min}^{-1}$) is measured by indirect calorimetry. It may also be predicted by the utilization of a submaximal exercise test from which the results are extrapolated to estimate maximal ability [14] via equation.

Regular moderate-vigorous physical activity and exercise result in increased cardiorespiratory fitness [3]. Current recommendations of the American College of Sports Medicine (ACSM), American Heart Association (AHA), and the *2008 Physical Activity Guidelines for Americans* prescribe at least $30 \text{ min} \cdot \text{d}^{-1}$ of moderate intensity exercise on at least $5 \text{ d} \cdot \text{wk}^{-1}$ [15, 19, 20]. Research also indicates that more vigorous physical activity requires less time and results in similar, and potentially greater, cardiorespiratory benefits [3], though this relationship will be specific to each element underlying cardiorespiratory fitness.

Routine participation in cardiorespiratory exercise (also commonly referred to as aerobic or endurance exercise training) results in various physiological adaptations in the heart, vasculature, and skeletal muscle that promote increases in cardiorespiratory fitness. One major structural change that occurs during training is an increase in the volume of the left ventricle. This adaptation reduces the energetic costs of the heart by increasing stroke volume, reducing resting heart rate, and reducing submaximal exercise heart rate.

Skeletal muscle also undergoes significant adaptations that promote an increase in cardiorespiratory fitness. First, an increase in vascularization of the skeletal muscle occurs as more capillaries form around individual fibers. This increase in capillarity results in a greater perfusion of the skeletal muscle, especially during exercise, increasing oxygen delivery to and extraction by the fibers. Skeletal muscle also undergoes various metabolic adaptations, including increase in mitochondrial content of the individual fibers, as well as increases in various key enzymes important for the uptake and oxidation of glucose and triglycerides.

Collectively, these adaptations are essential to the favorable changes that occur in various cardiometabolic risk factors that are associated with physical activity and exercise. Improvements in blood lipid profiles, reductions in insulin resistance, and reductions in systemic markers of inflammation have routinely been found as a result of regular physical activity, independent of weight loss [3].

Muscular Strength and Endurance

Muscular strength and muscle endurance have been combined to describe muscular fitness [13]. *Muscular strength* is related to the amount of external force a muscle or a muscle group can exert. Standard measurement of muscular strength requires the use of dynamometers or tensiometers to measure force produced during an isometric (non-shortening) contraction. Other tests, such as a 1-repetition maximum (1-RM) are more commonly used to determine this value, and measure dynamic, rather than static, strength. The 1-RM is defined as “the greatest resistance that can be moved through a full range of motion in a controlled manner” [14]. Muscular strength should always be measured in the muscle group of interest to a particular task. *Muscular endurance* is defined as the ability of a muscle or muscle groups to repetitively produce external force without undue fatigue. The standard of measure is through use of isokinetic dynamometer, but is more often determined

through tests such as sit-ups, sit-and-stand, push-ups, and pull-ups. Dynamic tests using free weights may also be used to determine absolute muscular endurance (total number of repetitions at a given resistance) or the relative muscular endurance (total number of repetitions at a resistance equal to percentage of 1-RM).

Resistance training promotes skeletal muscle hypertrophy and increased skeletal muscle fiber size through an increase in protein synthesis. Resultant increases in muscle fiber size and fiber density result in an increased muscular strength and muscular endurance. This also can result in increased lean body mass and a greater percentage of lean body mass to overall mass. Regular resistance training can also result in increased neural motor unit firing rates, recruitment of higher threshold motor units, and more synchronous motor unit firing [21]. In fact, these neural adaptations are largely responsible for early increases in muscular strength and endurance, as individuals adapt to the complex movements of resistance training.

Because adaptation is specific to the applied exercise stressor, strategies to promote muscular strength and muscular endurance are distinct. For promoting increases in muscular endurance the American College of Sports Medicine (ACSM) recommends a minimum of 10-15 repetitions for each major muscle group 2-3 days per week ($d \cdot wk^{-1}$) [17]. For increases in muscular strength, it is recommended that a minimum of 1-3 sets consisting of 8-12 repetitions at 70-85% of 1-RM be performed 2-3 $d \cdot wk^{-1}$ [17]. It is important to progressively increase the resistance so that a continual overload is applied to the muscle as adaptations occur. Resistance training can be completed through the use of specialized machinery, which assists movements, or free weights, and the choice of equipment should be based on experience level of the individual.

Body Composition

Another component of fitness is *body composition*; defined as the measurement of the relative amounts of body fat, lean tissue (i.e., muscle), bone, and other vital organs. These values are all obtainable through dual-energy X-ray absorptiometry (DEXA) or other scanning technologies. However, other more cost- and time-effective measurements (such as multiple site skinfolds and body mass index) are more commonly used as indices of body composition. Skinfolds assume that approximately 1/3 of all body fat is located subcutaneously, but this is largely influenced by race, ethnicity, and age [22]. To account for these variables, specific regression equations can be used to determine the percentage of body fat from skinfolds [23], though anthropomorphic equations always contain some amount of error. Body mass index (BMI) is a commonly used calculation to assess body mass (in kg) relative to height (in meters) of an individual. Naturally, the calculated BMI values cannot distinguish between lean body mass and fat mass, but a $BMI \geq 30 \text{ kg} \cdot m^{-2}$ is associated with an increase in health related risk factors [24].

Flexibility

Flexibility is also a component of overall fitness and is defined as the ability to move a joint about its full range of motion [12, 14]. Flexibility can be separated into two specific

types: static and dynamic. Static flexibility is ability to reach a specific point in the range of motion of a joint whereas dynamic flexibility is the ability to move quickly throughout the entire range of motion without resistance [21]. Good flexibility is an important to improving quality of life and mitigating joint pain and injuries, especially in aging populations.

Standard laboratory methods are used to determine flexibility, measured in degrees, through the use of goniometers. Less accurate methodology using tape-measures (i.e., sit and reach tests) are often used to evaluate flexibility at the hip clinically [14]. Just as muscular strength is specific to muscle groups, flexibility is joint specific and can be influenced by joint type and muscle “tightness” [14].

Here we have introduced and briefly discussed physical fitness, the underlying health-related components of physical fitness, and some standard measurement procedures. For more thorough discussion regarding these topics, we suggest you consult the appropriate citations or exercise science textbooks. For the purposes of this chapter, we will now focus mainly on the effects bariatric weight loss surgery’s effect on changes in cardiorespiratory outcomes.

BARIATRIC WEIGHT LOSS SURGERY, CARDIORESPIRATORY FITNESS, AND PHYSICAL ACTIVITY

Low cardiorespiratory fitness results in increased incidences of cardiovascular disease, all-cause mortality, and an increased relative risk of death similar to those associated with diabetes and tobacco use [2, 9, 25-31]. Furthermore, post-surgery complications and 30-day readmission rates were significantly related to cardiorespiratory fitness levels prior to surgery [32]. However, very few studies have analyzed changes in cardiorespiratory fitness following surgery. Also concerning is evidence that a significant portion (~30%) of weight loss may be due to loss of fat free mass [33, 34]. In the following section, we will discuss the limited available evidence regarding changes in cardiorespiratory fitness, changes in physical activity fitness, and the relationship between long-term weight loss and physical activity following weight loss surgery.

Does Weight Loss Surgery Result Enhance Cardiorespiratory Fitness?

de Souza et al. (2010) showed that $\text{VO}_{2\text{max}}$ was significantly increased (22.1 ± 2.1 vs. $15.8 \pm 2.1 \text{ ml} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) 12 months following RYGBP. Reductions in BMI in this cohort were also significantly correlated to exercise capacity [6]. To date, this is the only investigation to study bariatric surgery and changes in cardiorespiratory fitness through indirect calorimetry. Leite et al. (2013) found similar results using the six-minute walk (6MWT), an indirect surrogate for cardiorespiratory fitness in which individuals walk for 6 minutes and try to cover as much distance as possible. Sixty-five individuals who had undergone surgery in the previous 24 months and had a current BMI $< 30 \text{ kg/m}^2$ covered similar distances in the 6MWT to that of non-obese controls and significantly more than individuals who had undergone surgery but were still considered obese with a BMI $> 30 \text{ kg/m}^2$ [35]. Similar results were found by Varga et al. (2013), in which reduction in BMI correlated with significantly increased 6MWT three months following surgery [36].

Interestingly, two studies by the same group have studied the effect of weight loss surgery on functional measures of pulmonary function. Only one study found an increased lung volume (3.5%), increased expiratory reserve volume (88.9%), and decreased inspiratory reserve volume (-20.4%) 12 months following RYGBP [35, 37]. More controlled analyses will be required, but these data indicate that bariatric weight loss surgery may result in significant positive cardiorespiratory benefits.

Does Weight Loss Surgery Result in Spontaneous Increases in Physical Activity?

Reduction in weight following surgery presents the opportunity for individuals to increase physical activity levels, as physical limitations are eased. Available evidence indicates that patients routinely report increased levels of physical activity through the use of various lifestyle questionnaires (Table 1). However, self-reporting physical activity levels using questionnaires was recently brought into question by Bond et al. (2010). Their investigation found that patients significantly over-estimated the amount of time spent doing moderate-to-vigorous physical activity (MVPA; defined as a metabolic equivalent (MET) ≥ 3) and compliance (55% vs. 5%) with the recommended 150 min·wk⁻¹ of physical activity when reported levels were compared to the use of accelerometers [38], which provide objective measures of PA.

Evidence from Structured Exercise Interventions Following Weight Loss Surgery

Even though these findings regarding over reporting are concerning, reported increases in post-operative physical activity levels have been associated with enhanced outcomes. A recent meta-analysis of 17 observational studies by Egberts et al. (2011) found that increased post-operative physical activity resulted in an average of 3.62 kg greater weight loss than those who had minimal physical activity. Of these 17 survey studies, 15 showed a positive relationship between physical activity levels and weight loss [52]. Mundi et al. (2013) and Josbeno et al. (2011) both found MVPA levels to be greater in those who lost $\geq 50\%$ excess weight from pre-surgery baseline. Other studies have found that self-reported levels of physical activity have been associated with successful weight loss [40, 43-45, 47, 53, 54], BMI reductions [40, 41, 50], decreased fat mass [50], and increased lean body mass [50]. Even in patients who have regained a significant amount of weight, physical activity has been associated with lower long-term weight regain [10]. It is likely that altered physical activity levels, along with other lifestyle modifications such as nutritional and psychosocial, play a crucial role in maximizing the long-term success of post-operative excess weight loss. Future objective studies that explore whether bariatric weight loss surgery leads to spontaneous increases in regular physical activity will be crucial to understanding the role of physical activity in successful long-term weight loss.

Table 1. Effect of physical activity on bariatric weight-loss surgery outcomes

[§] Mean of total absolute weight loss (kg). [§] Mean all time points combined.

While the previous section highlighted a lack of consensus about spontaneous PA changes with surgery, there is also a lack of consensus regarding routine structured exercise. Routine structured PA is largely considered to be beneficial to overall health outcomes for the general population, though very few studies have examined appropriate strategies for severely obese populations and post-surgical patients [16, 55-57]. Thus, investigations regarding prescribed exercise following bariatric weight loss surgery are scarce.

Shah et al. (2011) randomized individuals at least three months post-surgery into a high volume exercise program (HVEP) or control group. The HVEP consisted of 12 weeks of aerobic exercise at 60-70% of $\text{VO}_{2\text{max}}$ with a weekly goal of $\geq 2,000$ kcal/week expenditure. Despite significant increased total energy expenditure ($\text{kcal}\cdot\text{kg}^{-1}\cdot\text{day}^{-1}$), HVEP did not show significantly altered outcomes for cardiorespiratory fitness, changes in LBM, reductions in fat mass, or reductions in BMI as compared to the non-exercising controls [48]. Interestingly, individuals in the HVEP did have a beneficial change in post-prandial blood glucose response to an oral glucose tolerance test [48]. Castello et al. (2011) also studied the effects of prescribed aerobic training at four months post-surgery. Individuals exercised for 12 weeks at 50-70% of peak heart rate 3 d $\cdot\text{wk}^{-1}$ for 1 h $\cdot\text{day}^{-1}$ [58]. The aerobic training group saw similar reductions in weight loss and reductions in BMI but significant increase in the 6MWT as compared to the non-exercising control group [58]. A combination of resistance training (2 sets, 15 reps, 60-75% 1-RM) and aerobic training (30 min $\cdot\text{d}^{-1}$, 60-75% heart rate reserve; HHR: defined as difference between resting heart rate and peak heart rate) was completed 3 d $\cdot\text{wk}^{-1}$ for 12 weeks in surgery patients in the study by Stegan et al. (2011). Both the training group and non-exercising controls saw similar improvements in body weight, BMI, and aerobic capacity [59]. However, the combination training prevented reductions in muscle strength of major muscle groups as compared to non-exercising controls [59].

Together these studies do not show significant enhancements of surgical outcomes (excess weight loss and BMI reductions) with the addition of a post-operative exercise regimen. This may be due to the large reductions in weight already associated with weight loss surgery, which may confound each study's ability to identify significant differences. Furthermore, these studies follow these individuals for only 12 weeks, in which the time frame may not be long enough to identify the long-term benefits of exercise interventions in these populations. However, enhancements in glucose tolerance [48] and maintenance of muscle mass [59] was seen within these time frames, indicating positive health benefits.

OPTIMIZATION OF EXERCISE STRATEGIES FOLLOWING SURGERY

Until exercise specialists have more data concerning the effects of weight loss surgery on fitness and physical activity patterns, it is difficult to effectively prescribe exercise plans during the post-surgical period, either acutely or over the long-term. In general, addition of overall PA via increased aerobic exercise should facilitate fat loss while maintaining lean mass. Sufficient doses of aerobic exercise should also improve cardiorespiratory and cardiometabolic fitness. Accentuation of this prescription with some resistance training may ameliorate the losses in muscle mass seen in some post-bariatric surgery patients.

Current American College of Sports Medicine recommendations suggest 30 min $\cdot\text{d}^{-1}$ on 5 d $\cdot\text{wk}^{-1}$ at a moderate to vigorous (60-75% maximal capacity) for enhancements of

cardiorespiratory fitness [3, 14]. Maximal capacity may be determined in a variety of ways such as the $\text{VO}_{2\text{max}}$, maximal predicted heart rate (HR_{max} ; $\text{HR}_{\text{max}} = 220 - \text{Age}$), or the heart rate reserve (HRR; $\text{HRR} = \text{Maximal heart rate} - \text{resting heart rate}$). However, evidence suggests that $150 \text{ min} \cdot \text{wk}^{-1}$ of moderate to vigorous physical activity is effective at preventing weight gain, while additional amounts of time ($\sim 250 \text{ min} \cdot \text{wk}^{-1}$) can result in modest weight loss [60]. Exercise amounts greater $250 \text{ min} \cdot \text{wk}^{-1}$ may be required for prevention of weight regain in the previously overweight [60]. Until more controlled randomized trials regarding various exercise interventions exploring the amounts, durations, intensities, and modalities of exercise strategies are available, further recommendations for cannot be prescribed.

Until more precise studies are done in severely obese populations, a general recommendation would be the addition of 1-3 sets of resistance exercise to the aerobic exercise described above. This would consist of 8-12 repetitions at 70-85% of 1-RM performed 2-3 $\text{d} \cdot \text{wk}^{-1}$ in all major muscle groups [17]. The goal of these exercises should be prevention of decrements in muscle strength and muscle mass that are prevalent following weight loss surgery.

CONSIDERATIONS FOR FUTURE INVESTIGATIONS

We have highlighted two general areas in which further studies are needed using well-controlled designs and objective measures. The first of these is the assessment of overall physical fitness. More studies are needed using techniques such as graded exercise testing to identify the individual and interactive effects of surgery and weight loss on various aspects of overall fitness such as cardiorespiratory fitness. In addition, there is considerable interest in the loss of lean body mass in certain patients following weight loss surgery, such that body composition longitudinal assessments are warranted, rather than relying on BMI (which does not speak to composition) to indicate morphologic changes. Fitness changes in patients are likely also modified by a litany of factors, including gender, age, and race, as well as baseline levels for fitness and history of physical activities. The second area we highlighted as needing more study is changes in physical activity levels after surgery-induced weight loss. While we reviewed a number of studies in the literature concerning physical activity in post-surgical patients, there is a severe lack of both objectively-measured general physical activity levels and purposeful prescribed exercise intervention studies to see how exercise affects tissues in the time period after weight loss surgery. Together, these data can be integrated to provide more precise exercise prescriptions post-surgery to facilitate health improvements.

Chapter 15

PREGNANCY AFTER BARIATRIC SURGERY

Department of Obstetrics and Gynecology, University Hospital of Santa Maria,
Centro Hospitalar Lisboa Norte, Lisbon, Portugal

OBESITY EPIDEMIC AND ITS IMPACT ON PREGNANCY

Obesity rates and its serious comorbidities have been rising worldwide resulting in a significant loss of life expectancy [1, 2]. Women of reproductive age are generally healthy and metabolic disorders in this age group are uncommon. However they account for a large group of the obese population and pre-pregnancy Body Mass Index (BMI) has been strongly associated with an increased risk of diabetes, hypertension and dyslipidemia, not only during pregnancy but also in the following decades of life. Pre-pregnancy overweight and obesity are also independent risk factors for serious comorbid cardiovascular events (ischemic heart disease, cardiac heart failure) even in the absence of metabolic syndrome [3-5].

The Impact on Fertility

The excess of adipose tissue has been demonstrated to be associated with increased secretion of a wide variety of cytokines and hormone-like factors, such as leptine and acute-phase proteins [6, 7]. The proinflammatory state and the metabolic dysfunction may justify the higher rates of infertility in obese women, particularly in the case of polycystic ovary syndrome (PCOS). The pathophysiology of PCOS is unclear and this entity is commonly defined as oligo- or anovulation, hyperandrogenism, and polycystic ovaries. This condition affects 6-25% of reproductive-age women and at least half of the women with PCOS are obese, representing potential bariatric surgery patients [8].

There are various reports of the negative impact of obesity on the success of assisted-reproductive technology (ART) [9]. Hirshfeld-Cytron et al. described a case of a woman that had been submitted to a gastric bypass with the loss of approximately 79 Kg and who

presented for controlled ovarian hyperstimulation, which resulted in an empty follicle syndrome, resolved by changing the route of administration of human chorionic gonadotropin (hCG). The authors hypothesized that in the setting of dramatic weight loss after bariatric surgery, skin redundancy may limit the bioavailability of subcutaneous hCG. This limitation was overtaken by changing the route of administration to intramuscular [10]. Several publications have also discussed the role of weight loss in obese women with infertility, in particular the specific role in improving the rates of conception and live births [11]. Nonetheless, the heterogeneity of the samples and of the outcomes in the published studies resulted in no consensus on the effect of maternal weight on the outcomes of ART [12].

Obesity and Pregnancy

Obesity in pregnancy is defined as a pre-pregnancy BMI ≥ 30 Kg/m² [13]. BMI is an independent predictive risk factor of maternal-fetal adverse outcomes [14-16]. The recommended total weight gain for overweight (BMI 25-30 Kg/m²) and obese women is 7.0-11.5 kg and 5.0-9.0 kg, respectively, based on the guidelines of the Institute of Medicine [17]. Extreme obesity (BMI ≥ 50 Kg/m²) imparts a significant increase of obstetric complications such as hypertensive disorders of pregnancy and gestational diabetes, macrosomia, shoulder dystocia, perineal trauma at birth and higher rates of cesarean deliveries, compared to all-other obese and non-obese women. Furthermore, neonates from extremely obese women are more likely to have metabolic disturbances and to be admitted to the Neonatal Intensive Care Unit (NICU) [18-20].

Regarding the higher risk of diabetes, it is generally accepted that the underlying mechanism consists on an exaggerated insulin resistance that is characteristic both of the pregnant and of the obese woman [21].

Obese women are prone to develop metabolic syndrome with all its typical components such as hypertension. Hypertensive disorders including preeclampsia (association between hypertension and proteinuria during pregnancy or in the postpartum period) and eclampsia (preeclampsia with convulsions) are more frequent in the obese population. It is hypothesized that obesity in pregnant women predisposes to preeclampsia due to an up-regulated systemic inflammatory reaction and hyperlipidemia [22, 23].

Obesity: Difficulty of Ultrasound Screening and Risk of Malformations

Obesity in pregnancy poses difficulties in the ultrasonographic diagnosis of fetal anomalies even for experienced sonographers [24]. Images are more difficult to interpret because of abdominal adiposity. A recent report has found higher number of ultrasound evaluations in this population. Among obese women, 48% had five or more ultrasound scans compared to 25% in the nonobese group ($p < 0.05$) [25]. Despite the technical difficulties, literature points out an increased ultrasound detection of specific structural anomalies, such as neural tube defects, cardiovascular, face and limb anomalies, when comparing to average-weight women [26, 27]. Some recent studies in animal models have demonstrated that maternal obesity may not only be associated with lifelong deleterious metabolic effects on the developing child such as all the underlying comorbidities (diabetes, hypertension...space

removed) but may also imply future neurologic disorders. The explanation of the investigators relies on alterations on neuronal proliferation, maturation and migration in association with the abnormal hormonal and inflammatory environment characteristic of obesity [28, 29].

Maternal obesity has been associated with increased risk of developing asthma during childhood. Furthermore, children's overweight is also an important predisposing factor and in both cases the mechanism that justifies the relationship between obesity and asthma seems to be an excess of inflammatory reaction [30].

Obese women have a higher incidence of dizygotic twin gestation when compared to average weight women. The possible explanation for this association relies on the elevated follicle-stimulating hormone levels [31].

A large study from Sweden including 1,599,551 deliveries, demonstrated that maternal overweight and obesity were associated with higher rates of spontaneous and medically indicated preterm deliveries, especially extremely preterm compared to normal weight women. [32]

Regarding the route of delivery, pre-pregnancy obesity imparts a higher risk of cesarean section. A systematic review on the risk for cesarean deliveries in obese nulliparous women demonstrated that the risk for cesarean delivery is increased by 50% in overweight women and is more than double for obese women compared with women with normal BMI [33]. Longer first stage of labor and higher rate of fetal heart rate abnormalities are contributors to the increased rate of cesarean deliveries [34-35]. Moreover, a cesarean section in an obese woman is associated with more frequent perioperative morbidities, such as longer operative times, excessive blood loss, anesthetic difficulties (epidural failure, difficult intubation), infectious and thromboembolic events. Obesity is also associated with short-term perinatal risks of macrosomia, birth trauma and shoulder dystocia [35, 36].

Lifestyle interventions (diet, exercise) in overweight and obese pregnant women give important contributions in reducing maternal complications such as hypertensive disorders, diabetes and shoulder dystocia. It is absolutely essential to encourage weight loss at the pre-conception counseling appointments since it has been proven that the pregravid excess of weight implies a higher risk pregnancy compared to the excessive weight gained during pregnancy. All the comorbidities that have been described above will result in longer hospital stay leading to increased overall healthcare costs compared to average weight women. Unfortunately lifestyle interventions are frequently ineffective in the long-term achievement and maintenance of weight loss. Furthermore, there are no truly effective pharmacological agents to treat obesity, especially morbid obesity [37-38].

TYPES OF BARIATRIC SURGERY: ADVANTAGES AND LIMITATIONS FOR PREGNANT WOMEN

Bariatric surgery is recommended for the treatment of morbid obesity ($\text{BMI} \geq 40\text{Kg/m}^2$) or class II obesity ($\text{BMI} \geq 35\text{Kg/m}^2$ with associated co-morbidities) and it is an increasingly selected option for obesity refractory to lifestyle intervention and medical treatment. It is the most effective approach to these situations, resulting in partial or complete resolution of co-morbidities associated with obesity and improving the quality of life of the patients.

Epidemiological studies report that women of reproductive age account for about half of the patients that have been submitted to bariatric surgery [39, 40].

Bariatric surgery comprises two major types of surgeries according to the main mechanism of weight loss: restrictive or malabsorptive. Restrictive procedures, such as adjustable gastric band, contribute to the limiting of caloric intake by reducing gastric volume, implying only mild nutritional deficiencies. Malabsorptive surgeries, such as biliopancreatic diversion, induce weight loss by generating an asynergy between the bolus and the biliopancreatic secretions, subsequently implying a higher protein and micronutrients (iron, calcium, vitamin B12, folate and vitamin D) deficiency compared to exclusively restrictive procedures. Gastric bypass, the most common weight loss surgery performed worldwide, is a technique that comprises both mechanisms of weight loss but is predominantly malabsorptive. Comparing the two most commonly used methods, laparoscopic adjustable gastric banding and Roux-en-Y gastric bypass, the last one is considered the most effective in terms of weight loss. Despite the longer operative time and the higher rate of perioperative morbidity associated with gastric bypass, in the long-term follow up, gastric banding requires more frequently reoperation. The majority of bariatric surgeries may be performed by laparoscopy with safer and less invasive procedures [41].

In nonpregnant obese patients, bariatric surgery contributes to reverse, eliminate or to improve many serious comorbid illnesses of the metabolic syndrome, such as impaired glucose tolerance, dyslipidemia and hypertension, leading in the long-term to an increase in life expectancy by decreasing the related deaths due to cardiovascular disease and complications. According to Buchwald et al., more than three quarters of patients with type 2 diabetes experience complete resolution of the disease after bariatric surgery. Of those patients who fail to achieve complete resolution, more than half showed demonstrable improvement. Thus, about 85% of patients with diabetes experienced improvement in their diabetes evolution after bariatric surgery [42]. Other medical conditions caused or aggravated by obesity, such as sleep apnea, daytime sleepiness, asthma, and gastroesophageal reflux are also significantly improved by the weight reduction after bariatric surgery. Moreover there is significant improvement in the quality of life and psychosocial wellbeing of morbidly obese patients [43]. Hormonal and mechanical factors of pregnancy alter the structure and function of the normal physiological barriers to reflux of gastric contents into the esophagus, and overweight is an aggravating factor that predisposes to complaints refractory to lifestyle and medical treatment. Thus, bariatric surgery as an effective promoter of weight reduction contributes to avoid the aggravating effect of obesity in physiological changes that are characteristic of pregnancy and otherwise would be symptomatic and difficult to control.

Several studies report an important improvement in fertility after bariatric surgery, particularly in hyperandrogenic and anovulatory women, independently of the type of bariatric surgery [40].

Potential complications such as micronutrient deficiencies are more commonly associated with malabsorptive surgery than with restrictive bariatric surgery. Restrictive procedures such as adjustable gastric band may be loosened during pregnancy permitting the individualization of caloric and gastric volume reduction. These surgeries are also less frequently responsible for late surgical complications than predominantly malabsorptive surgeries, such as gastric bypass. The band consists of an inflatable balloon whose diameter can be adjusted in ambulatory care by adding or removing saline solution via a reservoir port positioned beneath the skin. The bands are adjustable to allow the size of the gastric outlet to be modified as

needed in order to be adequate for gestational age weight gain. There are no randomized trials comparing elective deflation versus indicated deflation of the gastric band during pregnancy in terms of maternal-fetal outcomes. A recent retrospective study suggested that band loosening should be reserved for symptomatic patients in order to avoid excessive weight gain [44].

Pregnancy should be postponed until at least 12 to 18 months after bariatric surgery in an attempt to avoid the theoretical potential adverse effect of the intense nutritional deficiencies that may affect both fetus and mother during the rapid weight loss phase. If this vulnerable time period coincides with the time of elevated nutritional needs of a pregnancy, some reports highlight the possibility of a malnourished fetus and of potential complications such as low birth weight and malformations [45, 46]. Despite the inconsistent scientific evidence that supports the need to postpone pregnancy for a specific period after bariatric surgery and the lack of randomized trials showing significant differences in maternal-fetal morbidity and mortality, a recent retrospective cohort study, that compared pregnancy outcomes between women who conceived less than two years and more than two years after bariatric surgery, found that in the first group there were higher rates of gestational diabetes and lower weight loss [46]. Nonetheless, in case of pregnancy in the first year after surgery, women should be reassured that there is no scientific evidence of increased adverse neonatal outcomes. [47].

The American College of Obstetricians and Gynecologists (ACOG) recommends effective non-oral contraception, especially in women that have undergone malabsorptive surgery and do not pretend or have formal contraindications to get pregnant [48]. Oral contraception, especially after malabsorptive surgeries, may suffer a limited and irregular absorption leading to unreliable pharmacological effectiveness.

Regarding anatomic gastrointestinal complications, data from several reports suggest that they are more frequently associated with malabsorptive surgeries such as gastric bypass. Dumping syndrome consists on the effect of fast absorption carbohydrates that are rapidly emptied into the small bowel causing an osmotic shift of excessive fluid from the intravascular compartment to the small bowel lumen. This will cause abdominal cramping, bloating, nausea, vomiting and diarrhea. Symptoms of tachycardia, palpitations, anxiety and diaphoresis may be due not only to intravascular depletion but also to the secondary hypersecretion of insulin, which results in hypoglycemia. As a result, patients develop an aversion to high-carbohydrate foods, which leads to major changes in their diet and eating habits. Pregnant women submitted to bariatric surgery usually do not tolerate the standard oral glucose tolerance test for screening of gestational diabetes. An alternative method that has been suggested includes the outpatient evaluation of fasting capillary blood glucose and a 2-hour postprandial sample for 1 week between 24-28 weeks of gestation (the gestational age recommended for the standard evaluation). Women with previous restrictive surgeries, such as adjustable gastric band, rarely develop dumping syndrome and usually tolerate the standard glucose challenge test [48].

Understanding the underlying mechanism of each type of bariatric surgery is critical for an adequate counseling of patients. Pregnancy after bariatric surgery is associated with significant decreased rates of hypertensive disorders and gestational diabetes as well as lower rates of fetal macrosomia, comparing to obese women who have not undergone bariatric surgery [47].

Concise guidelines for counseling and management of reproductive-aged women that have undergone bariatric surgery are lacking. Moreover, there is neither consensus on the

adequate management of pregnant women previously submitted to bariatric surgery nor specific recommendations on the role of the bariatric surgeon. Nonetheless, several international societies and committees recommend tight monitoring of maternal nutrition and vitamin supplementation as well as close supervision with the collaboration of the bariatric surgeon and nutritionist [48].

Nutritional Deficiencies

As mentioned above, nutritional derangements can occur after bariatric surgery. These are particularly severe and frequent after malabsorptive procedures. Macronutrient deficiencies such as protein–calorie malnutrition and fat malabsorption, deficiencies in fat-soluble vitamins in association with deficit of several micronutrients and minerals, particularly iron, folate, vitamin B12, vitamin D and calcium may occur after gastric bypass. Absorption of iron and folate are diminished because of reduced availability of acid in the gastric pouch and also due to the bypass of the duodenum, the major site for the absorption of these two micronutrients [40, 42].

Patients with morbid obesity (usually the population submitted to bariatric surgery) may develop secondary hyperparathyroidism and vitamin D deficiency. The abrupt weight loss imparted by bariatric surgery is frequently accompanied by the regression of secondary hyperparathyroidism and the improvement of vitamin D deficiency and bone turnover. Dietary calcium is mainly absorbed in the duodenum. After Roux-en-Y gastric bypass, food stream bypasses the majority of the stomach and duodenum, causing chronic calcium deficiency which may result in secondary hyperparathyroidism and vitamin D deficiency, counteracting the improvement caused by weight loss. There are reports of osteopenia and metabolic bone disease after bariatric malabsorptive surgery. Supplementation with vitamin D and calcium is recommended in these cases [49].

Absorption of food vitamin B12 occurs in the terminal ileum. However the absorption requires an adequate gastric acid secretion and the prior combination with intrinsic factor, which is produced in the gastric mucosa, and may be deficient in women previously submitted to gastric bypass.

Laparoscopic adjustable gastric band has been only associated with folate deficiency. The importance of normal levels in prenatal and first trimester assessments in order to avoid neural tube defects makes it fundamental to routinely monitor the levels of folate before and during pregnancy.

The absence of an adequate multivitamin supplementation may have important negative consequences for the fetus such as: cerebral hemorrhages due to vitamin K deficiency; microcephaly, hypotonia, microphthalmia and permanent retinal damage due to vitamin A deficiency; anemia due to vitamin B12 and iron deficiency and fetal deaths [50].

Pregnant women previously submitted to a bariatric operation should have a nutritional assessment preconception and during pregnancy for deficiencies of micronutrients. There is no consensus on the adequate nutritional supplementation during pregnancy and the daily doses are mainly extrapolated from observational studies and expert opinions. Vitamin B12 storage is enough for about 12 to 18 months. If replacement is needed, a daily oral dose of 500 mcg is recommended. However the lack of intrinsic factor may prevent intestinal absorption and weekly intramuscular injections of 1000 mcg are usually more effective. In

order to prevent anemia and neural tube defects, Beard et al. recommend that folate (400 mcg) and iron (50-100 mg daily) should be routinely supplemented during pregnancy. Furthermore, at least 1,000 mg calcium (maximum of 1,500 mg) is also recommended [50]. Vitamin A supplementation should be limited to 5000 IU per day in order to avoid retinoid embryopathy [48].

Nutritional monitoring should continue in puerperal women who are breastfeeding [48].

High restriction of the daily intake of calories or proteins is not recommended in the case of pregnancy after bariatric surgery, even if there is persistence of a high BMI, because caloric restriction may impair fetal growth.

MATERNAL-FETAL OUTCOMES AFTER BARIATRIC SURGERY

Despite the lack of rigorous randomized studies, pregnant women who have been submitted to bariatric surgery have lower rates of many adverse maternal and neonatal outcomes compared to pregnant women who are obese without bariatric surgery and pregnancy outcome is similar to that in the general population [47].

Pregnancy after Malabsorptive vs after Restrictive Surgeries

Pregnancy after gastric bypass is more consistently reported in the literature in association with serious complications such as bowel obstruction, dumping syndrome, hemorrhage and herniation compared to restrictive surgeries. Gastrointestinal complaints may mimic non-specific symptoms of pregnancy such as hyperemesis, esophageal reflux and uterine contractions, requiring a high index of suspicion in order to disclose them. Misdiagnosis or delayed diagnosis may lead to maternal morbidity and mortality. Recently, a cohort study showed an incidence of 1% of internal herniation during pregnancy, which is a potentially serious complication that requires immediate surgical intervention even in the absence of typical findings on imaging exams [51]. The enlarging gravid uterus imposes an increased abdominal pressure and cephalad displacement of the bowel, contributing to herniation, obstruction, potentially life-threatening bowel strangulation and sepsis, which may be lethal to both mother and fetus [47].

Gastrointestinal complications in pregnant women with previous insertion of a gastric band are rarer than after gastric bypass but some serious complications such as gastric ulceration, band erosion and slippage have been reported in the literature. [52-54].

Pregnancy increases the risk of gallstone disease due to decreased gallbladder emptying and motility as well as changes in the chemical components of bile (increased cholesterol saturation and decreased bile acid content). Acute cholecystitis is the second most common nonobstetrical surgical emergency during pregnancy, after acute appendicitis. The frequency of symptomatic gallstones after malabsorptive surgery is significantly higher than after restrictive procedures. This difference has been attributed to the rapid weight loss after malabsorptive techniques, which is thought to be an important factor in inducing gallstones formation postoperatively. Thus, the occurrence of pregnancy during the postoperative period

of maximum weight loss is an additional risk factor for cholelithiasis and its complications, such as cholecystitis and pancreatitis [55].

Fetal Outcomes after Bariatric Surgery

Obese pregnant women have higher rates of extremes of growth disorders - low birth weight and macrosomia -, probably due to higher rates of vascular complications and gestational diabetes, respectively. After bariatric surgery, all the metabolic changes related to nutritional deficiencies impart a decrease in the mean birth weight, consequently decreasing the rate of macrosomia and increasing the number of small for gestational age neonates compared not only to obese women without bariatric surgery but also in comparison to the general population [56]. Weintraub et al. compared pre- and post-bariatric pregnancies and reported more than 50 percent decrease in the risk of macrosomia [57]. Regarding the rate of fetal growth restriction there is no consensus in the literature. The role of nutritional deficiency as an important risk factor that may induce poor fetal growth may be balanced by the decreased risk of preeclampsia after bariatric surgery that may account for lower cases of fetal growth restriction in this context.

Fetal adverse outcomes include the risk of small for gestation age due to chronic nutrient malabsorption as well as the acute metabolic consequences of maternal fasting in case of prolonged symptoms of gastrointestinal obstruction. We have recently reported a clinical case of gastric rupture finding during a cesarean section in a woman with an adjustable gastric band [58]. Despite the obvious maternal morbidity with the need of partial gastrectomy, we discussed the fetal repercussion of the hemoperitoneum from gastric rupture as well as the effect of prolonged maternal fasting and metabolic acidosis. The poor nutritional status of the mother can be exacerbated by vomiting or nausea during pregnancy. When inadequately corrected during pregnancy, serious health problems may occur in the fetus, such as growth retardation and electrolyte imbalances. Probably too restrictive bariatric surgeries with an exaggerated limitation of nutrient intake would result in maternal malnutrition or starvation. Consequently the accumulation of ketone bodies would condition in extreme situation a fasting acidemia. It is still not known the exact effect of maternal acidemia on fetal acid base balance.

Multidisciplinary management of pregnancy with an active role of the bariatric surgeon is essential to disclose the need for immediate surgical intervention. Adjustable gastric band is a reversible bariatric surgery and deflation is a possible solution for women with gastric obstruction symptoms. It is absolutely essential to evaluate the effectiveness of this intervention and if symptoms persist after removal of fluid of the band it may suggest band slippage or gastric prolapse. With these suspicions surgical exploration should be a first option. Imaging exams should not be avoided with the fear of fetal harm, since the correct diagnosis of an obstruction or herniation may prevent fetal morbidity and death. Case reports of maternal deaths have been described in the literature, mainly due to a delayed diagnosis [59, 60].

Previous bariatric surgery is not an indication for the anticipation of delivery or for a cesarean section and both decisions should be made in accordance with standard obstetric criteria [48]. The increased rate of cesarean deliveries in some observational studies of pregnant women after bariatric surgery is associated with obesity, gastrointestinal

complications and medically indicated preterm delivery [61]. The bariatric surgery is not an established independent risk factor for cesarean section [56].

There is no evidence of increased delivery complications in pregnancy after bariatric surgery, such as low Apgar scores, meconium-stained amniotic fluid, NICU admission, perinatal mortality rate, congenital malformations. Moreover, there is also no difference in neonatal outcomes between malabsorptive and restrictive surgeries [62].

CONCLUSION

Prepregnancy obesity is a significant and independent risk factor for both adverse maternal and perinatal outcomes with an increased risk for gestational hypertensive disorders and diabetes. The combination of pregestational metabolic syndrome with the physiological changes of pregnancy imparts an increased risk for maternal disease such as chronic cardiac dysfunction. During labor, obesity increases the risk for cesarean delivery and the associated complications of anesthesia, infection, wound disruption and thromboembolism.

Diet, behavioral therapy, exercise and pharmacological treatment usually yield only modest results and weight loss is frequently regained in a short to medium period of time. Bariatric surgery is a promising treatment for morbidly obese women or in case of failure of lifestyle interventions and medical treatment. Weight loss after these surgeries is associated with an increase in fertility for obese women of reproductive age, especially if there is an anovulatory dysfunction. Pregnancy after bariatric surgery is safe and women are not at increased risk for adverse maternal and perinatal outcomes. Moreover, the major risks for many obesity-related gestational complications are decreased, especially the development of hypertensive disorders and gestational diabetes, as long as appropriate monitoring, nutritional control and efficient prenatal care are provided. Non-oral contraception is recommended during the period of maximum postoperative weight loss (12-18 months) in order to avoid potential risks of complications secondary to poor maternal nutritional status during this period. The most common pregnancy complications after bariatric surgery are nutritional deficiencies, which are easily treated with adequate supplementation. Multidisciplinary surveillance with the collaboration of bariatric surgeon, nutritionist and close obstetrical monitoring are needed to an early detection of any maternal or fetal complications related to previous bariatric surgery. Both obstetricians and surgeons have to consider these pregnant women as high-risk pregnancies, with the need of special care for nutritional assessment and supplementation, and monitoring for adequate weight management.

It is crucial for the obstetrician to know specifically which bariatric procedure the pregnant women had undergone in order to effectively make preconception counseling as well as to prevent and manage potential complications. Malabsorptive interventions impart higher nutritional deficiencies and more frequently are associated with gastrointestinal complications while restrictive procedures such as gastric banding are reversible and adaptable during pregnancy and may be loosened and adjusted to facilitate adequate gestational weight gain. Gastrointestinal complications during pregnancy after bariatric surgery may have only mild and nonspecific symptoms and may also overlap with common obstetric complaints. Late recognition may be life-threatening for both the mother and fetus.

In conclusion, pregnancy in women previously submitted to bariatric surgery is usually safe for the mother and the fetus provided that there is an adequate collaboration between high-risk obstetrician and bariatric surgeon.

²Orthopaedic and Traumatology Department,
“G. d’ Annunzio” University, Chieti, Italy

The first percutaneous vertebral augmentation was performed by Galibert and Deramond [1, 2, 3] in 1984 at the University Hospital of Amiens, France. In this case, polymethylmethacrylate (PMMA) was injected into the C2 vertebral body for a painful hemangioma, under fluoroscopic control, become successful in relieving chronic pain of the patient. This procedure began to be known as “Vertebroplasty”, a fluoroscopic-guided therapeutic technique consisting of introduction of a trocar into a vertebral body, followed by injection of an acrylic polymer to give a greater resistance to the vertebral body. This procedure was allowed to treat vertebral fractures or vertebral body collapses due to tumors or metabolic disorders. In 1987 Deramond and Galibert [4,5] published a report of a small number of patients affected by painful hemangiomas of the vertebral body treated with Vertebroplasty, with satisfactory pain control. The first use of this technique for the treatment of painful osteoporotic vertebral compression fractures (VCFs), was published in 1991. Vertebroplasty was little known in the United States until 1993, when the procedure was shown at the American Society of Neuroradiology annual meeting. After a year, Dion and Jensen [6] successfully treated the first patient in the United States, at the Virginia University. However, the first article about this procedure was published in 1997: 29 patients with osteoporotic vertebral compression fracture, showed an effective relief of painful symptoms in 90% of cases after treatment with Vertebroplasty [7, 8]. As published by the SIR (Society of Interventional Radiology) in 2003, the main indications for Vertebroplasty include: osteoporotic vertebral compression fracture older than 2 weeks and refractory to medical therapy, painful vertebra with extensive osteolysis or invasion secondary to benign or

* Corresponding Author’s Email: v.salini@unich.it.

malignant tumor and painful vertebral fractures associated to osteonecrosis. The contraindications are absolute and relative as: asymptomatic vertebral body compression fractures, active osteomyelitis of the target vertebra, coagulopathy, allergy to bone cement, patient condition improving upon medical therapy, prophylaxis in osteoporotic patients, and myelopathy originating at the fracture level [9, 10, 11]. The official practice guidelines for vertebroplasty were collectively prepared in 2009 by the Society of Interventional Radiology (SIR), the American College of Radiology (ACR), the American Society of Neuroradiology (ASNR), the Society of Neurointerventional Surgery (SNIS) and the American Society of Spine Radiology (ASSR). However, one of the most important problem related to Vertebroplasty is that this technique is not able to restore vertebral height. As a solution to this issue, a procedure called “Kyphoplasty”, also known as “Balloon-Assisted Vertebroplasty”, was introduced by Dr. Mark Reiley in 1990 [12] as an alternative vertebral augmentation technique, able to restore the height and angle of kyphosis of a fractured vertebra, followed by its stabilization injecting bone cement. The procedure consists in the use of a small balloon that is inflated in the vertebral body, in order to create a void within cancellous bone, followed by cement injection as PMMA. Subsequently, Kyphoplasty was proposed as an alternative procedure to Vertebroplasty, since Kyphoplasty is capable of correcting and preventing deformity of the spine and having a lower rate of cement extrusion. One of the most important trial was done by Wardlaw and al. in 2009 [13]. It was a randomized controlled trial (FREE): 300 patients, affected by one to three acute vertebral fractures, were divided into two groups. The first group (149 patients) was treated by Kyphoplasty whereas the second control group (151 patients) was treated conservatively. The results demonstrated that balloon Kyphoplasty was a safe and effective technique in case of acute vertebral fractures, usable especially as early treatment option. In a prospective randomized study, Liu et al. (2010) [14] randomly assigned 100 patients with osteoporotic vertebral compression fracture to either Kyphoplasty or Vertebroplasty and followed them for six months. The main results from this study was that there was a little difference between Kyphoplasty and Vertebroplasty in terms of pain reduction, but Kyphoplasty increased vertebral body height and reduced kyphotic wedge angle more than Vertebroplasty. In 2012 Ma et al. [15] in a systematic review and meta-analysis concluded that “*Kyphoplasty and Vertebroplasty are both safe and effective surgical procedures for treating osteoporotic vertebral compression fractures. Kyphoplasty may be superior to Vertebroplasty in patients with large kyphosis angles, vertebral fissures, fractures in the posterior edge of the vertebral body or significant height loss in the fractured vertebrae*”. Vertebroplasty and kyphoplasty are both excellent percutaneous surgical technique, capable to provide short-term pain relief and to improve physical functionality in patients with osteoporotic or tumor-associated vertebral fractures [16]. However, none of these two techniques is not free from complications such as symptomatic cement leakage, cement embolism, pulmonary embolism, hematomas, spinal cord compression, radiculopathy, infection and adjacent vertebral fracture (domino effect). This is one of the several issues that must be resolved [17]. Therefore, alternative percutaneous vertebral augmentation procedures become necessary. For these reasons nowadays the “third generation” of percutaneous vertebral augmentation procedures is started [18].

Chapter 17

THORACO-LUMBAR SPINE ANATOMY

Rosa M. Mirapeix*, MD, PhD

Human Anatomy and Embryology Unit
Department of Morphological Sciences
Autonomous University of Barcelona, Spain

INTRODUCTION

A good knowledge of the anatomical characteristics of the spine is essential to understand and to anticipate any problems that might occur during surgical practice. Moreover, the awareness of the normal relationships between the spine and the surrounding elements is becoming increasingly important in clinical practice, since surgeons are often asked to use advanced imaging procedures during surgery. Percutaneous vertebral procedures require, on the one hand, an accurate localization of the bone region to be treated and, on the other hand, a careful identification of the trajectory that must be followed for safe device insertion. The normal anatomic structures and variations that affect the spine must be understood in order to accomplish this goal.

The human spine is a complex unit made up of 24 vertebrae (7 cervicals, 12 thoracics and 5 lumbar), the sacrum (5 fused vertebrae) and the coccyx (4 fused vertebrae with Co1 often not fused).

The thoracolumbar vertebrae can be divided into the vertebral body, the pedicles, posterior elements and the transverse processes (these have a slightly different embryological origin and are not anatomically regarded as part of the posterior elements) (Figure 1).

The vertebrae progressively enlarge from the cervical through the lumbar region in all three planes despite finding variations in its size at any particular level, depending on individual's size, age and gender.

Figure 1. Parts of the vertebrae. 1- vertebral body; 2- pedicles; 3- posterior elements: articular processes (3a), laminae (3b) and spinous process (3c); 4- transverse processes.

THE VERTEBRAL BODY

The anteroposterior length of the thoracolumbar spine gradually increases caudally, whereas the transverse width decreases from T1 to T4 (from 30 mm to 25 mm) and then progressively increases until L5 (55 mm) [1].

The anterior surface of the vertebral body is slightly concave and it relates to the prevertebral muscles, the descending aorta and the inferior vena cava. From the posterior wall of the descending aorta, a paired branches that supply the thoracic and lumbar spine arise. These arteries run around the vertebral body towards the intervertebral foramina, giving off ascending and descending branches (radicular arteries), which anastomise with similar branches arising from the adjacent vertebral arteries from above and below. The anterolateral surface, as well as, the greater part of the superior and inferior surfaces of each vertebral body is perforated by tiny holes which are occupied by nutrient intraosseous arteries coming from the deep surface of each radicular artery. Accompanying the arteries that supply the vertebral spine and surrounding the vertebral body, there is an external vertebral venous plexus. This plexus has numerous connections along the trunk with the intercostal and lumbar veins. Intercostal veins connect with the hemiazygos and azygos venous system that finally drains into the superior vena cava, while lumbar vertebral veins drain into the inferior vena cava. These connections must be taken into consideration in order to prevent or diagnose local and distance side effects related to surgical procedures.

The posterior surface of the body has one or more large nutrient foramina which are occupied by nutrient arteries and the basivertebral veins. This surface of the vertebral body relates to the vertebral canal, which is occupied by the spinal cord, which is surrounded by the meninges. The space between the outer meninx (the dura mater) and the vertebra is called the epidural space. In the trunk, this epidural space is quite wide and is occupied by internal vertebral venous plexus and fat. The internal vertebral venous plexus is connected longitudinally along the entire vertebral spine. This valveless plexus consists of two venous groups (anterior and posterior), which communicate by a series of venous rings [2]. The anterior epidural network of veins is much more prominent than the posterior and it is related to the posterior longitudinal ligament, while the posterior epidural network of veins is related to the ligamentum flavum. The internal vertebral venous plexus drains into the external vertebral venous plexus through radicular veins at the intervertebral foramina region. The

existence of this epidural space should be borne in mind when invasive procedures are performed.

THE POSTERIOR ELEMENTS

The posterior elements of a vertebra are the laminae, the articular processes and the spinous processes (Figure 1). All these elements provide areas for muscle attachment.

The Laminae

The laminae (right and left) connect in the midline and close the vertebral canal posteriorly. In the lower thoracic spine, its thickness decreases slightly while its height increases, being T11 the tallest. In the lumbar spine, the thickness and width increases (L5 has the greatest width) [3]. In the thoracic spine, a degree of laminar overlap between the level above and the level below exists. In contrast, in the lumbar spine, the laminae have a wider interlaminar space; therefore the ligamentum flavum has a greater length. The portion of the lamina located between the superior and inferior articular processes and just below the level of the pedicle is called isthmus or pars interarticularis. This is the most common site of stress fractures [4].

The Articular Processes

Related to the lamina and located above and below the posterior end of the pedicles, there are four articular processes (two superiors and two inferiors). The articular processes of two consecutive vertebrae interlock at the facet joints. In the thoracic region, the articular facets are coronally aligned and markedly oblique (on average at 65° to the plane of the intervertebral discs), whereas in the lumbar spine these joint surfaces are more vertical and sagittally aligned. In the posterior edge of each of the superior articular processes of lumbar vertebrae, there is another small bump called *mammillary process*.

The Spinous Process

Projecting posteriorly from the junction of the two laminae we find the spinous process. Its length increases from T1 to T7 and decreases downwards. The tip of each spinous process, from T1 to T3 projects over the upper half of the underlying vertebra; from T4 to T6 it lies over the lower half of the underlying vertebra; from T7 to T9 it projects over the upper half of the subjacent vertebra, and from T10 to T12, the tip of the spinous process is at the level of the subjacent intervertebral space [1]. In the lumbar spine, the spinous processes are shorter and horizontally orientated. They are quadrangular and thickened along its posterior and inferior borders. The interspinous and supraspinous ligaments connect to adjacent spinous processes.

TRANSVERSE PROCESSES

They extend laterally from the junction of the pedicle and the lamina on each side as a flat rectangular bar of bone. In the thoracic region, the tip of each transverse process from T1 to T10 bears oval costal facets while T11 and T12 do not have costal facet since they do not articulate with the ribs. In the lumbar spine, near its attachment to the pedicle, each transverse process bears on its posterior surface a small, irregular bony prominence called the *accessory process* (identifiable as the only bony projection from the back of the proximal end of the transverse process). The length of the transverse processes progressively decreases from T1 to T12. The transverse processes of L4 are the smallest, thus allowing identification of a transitional vertebra [1].

PEDICLES

The pedicles are two pillars of bone extending backwards from the superior half of the posterior margin of the vertebral bodies. It is the only connection between the posterior elements and the vertebral bodies (Figure 1). Pedicles are designed to transmit the tension and bending forces sustained by any of the posterior elements to the anterior part of the vertebra. They have thick bone walls while their inner cores are filled with cancellous bone. The medial cortical wall is 2-3 times thicker than the lateral cortical wall [5].

In the thoracic spine, pedicles are ovoid in shape; their sagittal diameter is slightly larger than the transverse diameter [6]. Pedicle height increases from 9 to 16 mm [7], while pedicle width decreases from T1 to T10 (the narrowest between T3-T10) and has a mild increase from T10 to T12 with sizes ranging from 4 to 8 mm depending on the level [8]. In lumbar spine, pedicle height is fairly constant being 15 mm on average [9] while pedicle width increases progressively until L5, which is twice as wide as L1 [10]. Thus, in the thoracic spine the pedicles are narrower whereas in the lumbar spine they are wider.

Pedicles cannot be visualized directly from a posterior view. The location of the pedicle is inferred by identifying bony landmarks such as the transverse processes and the superior articular facets. Pedicles are in the horizontal plane, at the same level than the transverse processes. Thus, the midline of the transverse process corresponds to the mid-pedicle height. In the coronal plane, the pedicles are located anteriorly to the inferior half of the superior articular facet and to the isthmus of the lamina. Furthermore, the lumbar pedicles are located medially to the mammillary processes.

The direction of the pedicles from posterior to anterior varies along the thoracolumbar spine not only in the transverse plane but also in the sagittal plane (Figure 2).

In a transverse plane, the thoracic pedicles are almost parallel, running forward 0°, whereas in the lumbar spine they have a slight medial inclination (Figure 2A). From T12 to L5, one should aim 5° more medially for each level [6, 9] (Figure 2B). Thus, at the L5 level the orientation must be approximately 30° medially (the direction being from posterolateral to anteromedial). The interpeduncular distance normally decreases progressively from the level of T1 through T6 and then increases gradually from T6 to L5 [11] due to the transverse width of the vertebral body along the thoracolumbar spine.

In a sagittal plane, the pedicles exhibit varying angles based on both their anatomical characteristics and the amount of physiological lordosis found in each vertebral level. Lumbar pedicles are neutral (90°) for most of the lumbar spine except at L5, where they have a slightly cranial orientation [6] (Figure 2C).

Pedicles have important relations medially, superiorly and inferiorly. The vertebral canal is located medially to the pedicles. It is occupied by the spinal cord. It should be taken into consideration that they are in contact with the epidural space, which contains fat and an inner vertebral venous plexus. The distance from the medial pedicle wall to the lateral border of the dura mater is greater in lumbar spine (approximately 1.5 mm) than in the thoracic spine [12]. Superiorly and inferiorly, pedicles form the inferior and superior margins of the intervertebral foramina respectively. The distance between the nerve root and the superior pedicle wall varies from 1.9 to 3.9 mm in the thoracic spine and from 4.1 to 5.5 mm in the lumbar spine, while the distance between the nerve root and the inferior pedicle wall varies from 1.7 to 2.8 mm in the thoracic spine and from 1.3 to 1.5 mm in the lumbar spine [12, 13]. The spinal ganglion is located below the pedicle, on which it sometimes leaves its imprint [14].

Figure 2. Orientation of the pedicles. A) *Thoracic spine*. The thoracic pedicles run forward 0° . They are almost parallel. B) *Lumbar spine*. The lumbar pedicles run from posterolateral to anteromedial. C) *The L5 pedicles* have a slightly cranial orientation.

THE INTERVERTEBRAL FORAMINA

The intervertebral foramina are bounded above and below by the pedicles, anteriorly by the posterior surface of the discs and body vertebra and posteriorly by the zygapophysial joints. There is, however, a great variation in their size during movements. The foramen is larger in flexion and smaller in extension, being a difference of about a 20% between both situations. In extreme flexion, the pedicles move apart from each other and the disc's convexity is minimal due to the tension of the posterior longitudinal ligament [14]. During extension, all the diameters decrease: the pedicles move closer to each other, reducing the

height of the foramen. In the thoracic region, the heads of the ribs occlude the inferior part of this foramen. In the lumbar region, the intervertebral foramina are oval with a large vertical axis. The L5-S1 foramen is the roundest and the smallest [14].

In adults, the 7-22% of the intervertebra foramina are occupied by the radicular arterioles, the foraminal veins, the lymph vessels, fat and the spinal nerve which maintains a relatively constant location in the anterior superior portion of the foramen [6].

ETIOPATHOGENESIS OF PATHOLOGICAL AND TRAUMATIC VERTEBRAL FRACTURES

Vincenzo Levi*, MD and Mauro Pluderi, MD

Neurosurgery Department, IRCSS Ca' Granda - Ospedale Maggiore Policlinico,
“Milan University”, Milan, Italy

INTRODUCTION

Fractures of the thoracolumbar spine are the most common fractures of the spinal column. They are usually provoked by compression forces, though flexion/distraction, hyperextension and rotation are the main mechanisms responsible for high instable lesions. Epidemiologic data on thoracolumbar fractures are not uniform worldwide. In Western countries, more than 160,000 thoracolumbar fractures occur every year. The estimated prevalence among the adult population is approximately 1% , but this percentage increases up to 2-3% considering subjects older than 80 years. The sequelae of the damage caused by a vertebral fracture in the thoracolumbar segment of the spine may be devastating, including severe neurologic deficits as paraplegia, pain and secondary spine deformity.

Thoracolumbar fractures may be divided in pathological and traumatic fractures, depending on the etiology of the lesion. The former are usually the consequence of alteration of the vertebral bone's normal structure. They are sustained by different pathological conditions, such as osteoporosis, infections or tumours, and may lead to spontaneous fracture or collapse of the vertebra.

Traumatic fractures, instead, are often provoked by high-energy injuries, such as motor vehicle accidents and falls from height. They occur predominantly in the young and are responsible for the most unstable and severe lesions.

Aim of this chapter is to analyse the underlying mechanisms responsible for thoracolumbar fractures formation, both pathological and traumatic. Before discussing this topic, however, it is necessary to review few but essential anatomic and biomechanical concepts regarding the thoracolumbar region of the vertebral column.

ANATOMIC AND BIOMECHANICAL CONSIDERATIONS

As it is well known, each segment of the spine may be schematically divided in three columns (Denis, 1983):

- Anterior column: includes the anterior half of the disc and vertebral body and the anterior longitudinal ligament.
- Middle column: consists of the posterior half of the disc and vertebral body plus posterior longitudinal ligament and pedicles.
- Posterior column: encloses vertebral posterior arch and interposed posterior ligamentous complex (supraspinous and interspinous ligament, facet joints and capsule, ligament flavus).

At the time of trauma, compressive and/or distraction forces act on one or more of these columns, producing bony and ligamentous damage, that in some cases (when two columns are involved at least) may lead to acute instability and consequently neurological deficits.

The thoracolumbar region, moreover, is more susceptible to fractures because of the following anatomical reasons:

- At the transition T11–12 the spine curvature switches from a relatively rigid thoracic kyphosis to a more mobile lumbar lordosis.
- The lowest thoracic ribs (T11 and T12) are free floating, providing less stability at the thoracolumbar junction.
- Different joint range of motion on the antero-posterior and lateral planes between the thoracic and lumbar region, mainly due to the diverse facet joints orientation. The thoracic facet joints, in fact, are mostly oriented in the coronal plane, in opposition to the lumbosacral segment where they are oriented in a more sagittal alignment, increasing in this way the degree of potential flexion and extension at the expense of limiting lateral bending and rotation.

The thoracolumbar segment, therefore, represents a point of great transition between the stiff thoracic cage and the more mobile lumbar spine. This basically explains why the thoracolumbar region is most commonly involved with traumatic spinal fractures.

PATHOLOGICAL THORACOLUMBAR SPINAL FRACTURES

Pathological fractures of the thoracolumbar spine may be caused by several diseases, as bone infections (osteomyelitis, tuberculosis), metabolic bone (osteoporosis, osteomalacia, hyperparathyroidism) and tumours (multiple myeloma, primitive and metastatic tumours).

Among these entities, the osteoporosis results to be the most common cause of pathological thoracolumbar spinal fractures. In the European Union, in 2000, the number of osteoporotic fractures was estimated at 3.79 million, whereas the incidence in women older than 50 years is greater than 10 per 1000 per year and is three times higher after the age of 75

years. Considering these data, 30–50% of women and 20–30% of men will develop vertebral fractures during their life.

Osteoporosis generally produces a kind of fracture that is referred as compression or wedge –shaped fracture, defined as a vertebral body height reduction at least of 15%. A wedge compression fracture is generally a mechanically stable fracture pattern.

Unlike traumatic fractures in which pain decreases with time as the fracture heals, pathologic fractures secondary to bone infection, tumor or osteoporosis usually have pain that worsens over time.

TRAUMATIC THORACOLUMBAR SPINAL FRACTURES

The thoracolumbar region of the spinal column represents the most common site of traumatic vertebral fractures. In a cohort of 965 patients admitted for traumatic spine injuries to the Emergency Department in the Australian State of Victoria, Tee et al has recently found the incidence of thoracolumbar spine injuries to be more than 60%, with compression fractures being the most common injury morphologically.

In literature, neurological deficiencies has been reported in a range of 20% and 30% of the cases, depending most of all on the fracture type and the trauma severity. Approximately, 60% of traumatic fractures occur at the thoracolumbar junction (T11–L2), whereas 30% and 10% affect the thoracic and lumbosacral segment of the spine respectively.

Motor vehicle accidents results to be the main cause of vertebral injury in the young population (50%). The remaining fractures are secondary to falls from height and sports and recreational activities.

The most relevant forces that may be implied in the pathophysiology of thoracolumbar trauma and fractures are:

1. *Axial compression*: if it is the only force implied in the trauma, it causes an isolated failure of the anterior column, usually leaving posterior column elements intact. The consequence is a loss of integrity of the vertebral endplate, which may be followed by vertebral body compression and then by typical burst fracture. Depending on the energy of the trauma, the axial load may produce an incomplete or complete burst fractures. Whether severe compression occurs, instead, significant disruption of posterior elements may arise as well. Wedge compression fractures, conversely, are the result of the combination of an axially compressive force plus an eccentric compressive force anterior to the axis of rotation.
2. *Flexion/distraction*: when a flexion/distraction force is applied to the spine, the axis of flexion is moved anteriorly (towards the anterior abdominal wall), producing large tensile forces on the vertebral body and posterior arch. The consequent structural damage may interest all the elements of the spine (osseous structures, ligamentous apparatus, soft tissues).

Chance fracture is a typical distraction fracture that involves a horizontal fracture, which begins in the spinous process, progresses through the lamina, transverse processes, and pedicles, and extends into the vertebral body. The cause is usually a motor vehicle accident

with the victim wearing a lap seat belt.

1. *Hyperextension*: Hyperextension produces an extremely unstable injury pattern that may be biomechanically considered the reverse of that seen with flexion. Tension, in fact, is applied anteriorly to the strong anterior longitudinal ligaments and anterior portion of the anulus fibrosus, which are usually severely damaged, whereas compression forces are transmitted to the posterior elements. This mechanism results in a rupture from anterior to posterior and may result in facet, lamina, and spinous process fractures.
2. *Rotation*: both compressive forces and flexion-distraction mechanisms may be combined with rotational forces and lead to rotational fracture dislocations. In this case, the anterior and posterior elements may be completely pulled away. This pattern of fracture is highly unstable. Rotational forces may further be combined with shearing forces and lead to even more unstable fractures (slice fractures, Holdsworth).

The spine acts as a pillar, since it supports the weight of the upper part of the body, by transferring the load on the lower limbs through the pelvis [1]. The spine is conceptually divided into several Spinal Functional Units (SFU). Each SFU is composed of two vertebrae and the disc in between them. Each SFU could be divided into three columns: anterior, middle and posterior. The anterior and middle columns sustain the axial compressive loads that become progressively more important cranio-caudally. A complex load resulting from an anterior bending moment and an axial compression, due to the specific location of center of gravity of human body, that is situated anteriorly to the spine [1,2]. For these reason, tensile forces along the posterior column are necessary in order to keep the spine erect. This forces act on the medial column, that represents the fulcrum of the spine, while the anterior column has to resist the compression forces. Consequently to the anterior flexion, center of gravity of human body moves more anteriorly, increasing the bending moment on the vertebral column and the compressive stresses on the anterior column. Bending over to pick up a load not only moves the center of gravity anteriorly, but also it increases the magnitude of the anteriorly load, which combined with the increased moment arm, greatly increases the compressive stresses on the anterior column. This biomechanical condition is responsible of the anterior overload, especially in the older people with camptocormic posture, further overloading the anterior column.

Vertebral body is formed by cancellous bone biomechanically characterized by high bone turnover (80%) and lower calcified volume (20%). Therefore, this tissue withstands the dynamic stresses, deforming itself without breaking. Vertebral body resists the compressive forces, although this function depends on age, posture and loading history. Resistance to

* Corresponding Author’s Email: danielevannimd@libero.it

compression is attributable to the dense trabecular network. Infact, the structure of a vertebral body does not weaken greatly even after removal of the outer shell of cortical bone,. On the osteoporotic vertebrae, the cortex resists 15% of the compressive load close to the endplates, and 45% at midbody height. The supporting role of the cortex increases in vertebra of older patients. In fact they lose bone faster from the trabeculae that from the cortex. The anterior cortex is thicker and less porous than the posterior one. Probably this is due to the need to resist to the higher forces during the forward flexion movements. The trabeculae of the vertebral bodies tend to be denser in the posterior part of the vertebral body, compared to the anterior part. The trabeculae are more dense in the inferior part than the upper half, perhaps because they are reinforced by the trabecular arcades from the pedicles. Degenerative disc disease and senile neuromotor and neurosensory decay, are associated with progression of kyphosis resulting in anterior translation of gravitational axis, progressive distraction of posterior ligaments and compression of anterior column. In case of osteoporosis, the trabecular thinning results in reduction of strength of vertebral body.. In relation to the gravitational force, the fracture of the body induces reduction of height of vertebral body and progression of kyphosis, especially at the level of the anterior spinal column [4]. The more involved vertebrae are T7 and T8 at the middle thoracic column and T12 and L1 at the thoracolumbar transition which is subjected to great flexion (Figure 1). The thoracolumbar hinge is subjected to most stress being a junction of different curves. The progression of kyphotic curve and forward displacement of gravitational axis lead to an increase in flexion, causing new fracture. Infact, the risk of another vertebral fracture increases 5 fold after the first event ('domino-effect') (Figure 2).

These conditions, must be considered in case of open approach, especially in identifying the level of junction and the location and surgery instrumentation, considering the increased fixation failure risk.

Chapter 20

EPIDEMIOLOGY OF ADULT THORACOLUMBAR FRACTURES

Luigi Aurelio Nasto* and Enrico Pola

Department of Orthopaedic Surgery, Catholic University of Rome School of Medicine,
“A. Gemelli” University Hospital, Rome, Italy

INTRODUCTION

Data on incidence of thoracolumbar (TL) fractures in adult population are sparse and varies with countries and population analysed. Reported incidence ranges from 23 to 90 cases per 100,000 inhabitants per year.[1-3] However, available data are either retrospective case series from different centres or small population cohort studies, i.e., the Framingham study which included 5,209 patients with a reported prevalence of vertebral fractures of 14%.[4]

Thoracolumbar fractures classically exhibit a bimodal distribution, with peaks among males under 30 years of age and in the geriatric population.[5] Thoracolumbar fractures occurring in young and middle-age patients (less than 60 years old) result from a medium to high-energy trauma, such as motor vehicle accidents, falls from height, and sports-related injuries. In particular, motorcycle riders are more likely to sustain severe spinal fractures; nevertheless, in recent years the incidence of thoracolumbar fractures resulting from gunshot wounds and other projectiles has been increasing as well. [6, 7] The rate of TL fractures in patients admitted to the hospital because of blunt trauma has been reported to be as high as 2-4%. In an observational study of 2400 trauma patients scanned for TL fractures, a total of 260 injuries were identified in 152 patients (6.3%). Forty-two (16.2%) fractures occurred at L1, 38 (14.6%) at L2, 29 (11.1%) at L3, and 27 (10.4%) at T12; the higher thoracic spine (T1-T7) accounted for 13.5% of the fractures, making the thoracolumbar junction the most frequently involved segment.[8] TL injuries occur most frequently in men (2/3) than in women (1/3) and some neurological deficit occurs in about 10 – 20% of traumatic spinal fractures, accounting for some 11,000 new spinal cord injuries occurring each year in the United States. In a recent longitudinal prospective study on 13,496 admitted patients in Sweden, incidence of TL

* Corresponding Author's Email: luigiaurelionasto@yahoo.it.

fractures in patients younger than 60 years old was 13 per 100,000 per year, and twice as high in men as in woman. Fifteen percent (15%) of these patients required surgery with a 30 day case fatality rate of 0.7% and a 90 day case fatality rate of 1.4%. [9] Despite the relatively low mortality rate of TL fractures in young patients without neurological injury, the 1-year mortality rate for patients with paraplegia or other catastrophic spinal cord injuries approaches 7%. [10]

Isolated thoracolumbar fractures are also frequently seen in elderly women. Because of their poor bone density and declining mental status, elderly people may develop TL fractures after a fall from a standing height or minor trauma. TL wedge compression fractures account for the most frequent osteoporotic fractures. They often occur at the midthoracic (T7-T8) spine and the thoracolumbar junction (T12-L1) and, despite being associated with significant pain and morbidity, remain frequently undiagnosed. [11, 12] Reported incidence of TL fractures in elderly patients rises sharply with age ranging from 570 to 1070 per 100,000 inhabitants per year, in men and women respectively. [13] Osteoporosis is the single most important risk factor for TL fractures in elderly patients, therefore TL fracture epidemiology is strictly dependent on the incidence of osteoporosis in general population. It is currently estimated that over 200 million people suffer from this disease worldwide. [14] This figure is expected to rise in the following years because of the alarming trend of an increasingly aging population in western countries. [15] Osteoporotic TL fractures also carry an extra burden of increased morbidity and mortality in elderly patient. In a recent long-term (12 to 22 years) follow-up study on 257 patients presence of an osteoporotic TL fracture strongly correlated with higher prevalence of back pain, impaired health status, and increased 10-year mortality rate. Mortality rate among female patients with a TL fracture was 95.1 per 1,000 inhabitant-years, whilst it was only 62.0 per 1,000 inhabitant-years among an age-matched control population. [16] TL fractures in elderly patients are associated with chronic pain, decreased physical function, deformity, and potentially social isolation, all of which negatively impact individual quality of life. [17] Nevertheless, a direct connection between TL fractures and specific causes of death have not been identified. This suggests an indirect association between osteoporosis, TL fractures, and other comorbidities eventually leading to a decreased life expectancy for elderly patients. [18]

Direct and indirect costs of TL fractures in general population have been studied by many authors but figures are different according to the country and the study population analyzed. [19-22] In a recent study by the researchers of the VU University Medical Centre in Netherlands, a total of 200 patients were retrospectively reviewed and assessed. Average cost of conservative treatment for stable TL fracture without neurological deficit was € 5,100. Surgical treatment of unstable fractures had an average cost of € 12,500, whereas TL fractures with neurological deficit accounted for € 31,900 of extra costs. [23] However, estimates of costs for osteoporotic TL vertebral fractures are even higher. A recent study from researchers at Hannover University has shown an extra average cost of € 8,200 per year per newly diagnosed fracture in patients ≥ 60 years of age. [24] The annual number of fractures in the EU will rise from 3.5 million in 2010 to 4.5 million in 2025, corresponding to an increase of 28% with a total cost, in 2010, of € 37 billion (of which 66% spent for direct treatment of the incident fractures, 5% for pharmacological prevention, and 29% for long-term fracture care). [25] With these figures in mind, it is reasonable to assume that the prevention, treatment, and long-term follow-up of TL fractures in Europe and worldwide will become a major issue for modern healthcare systems.

SURGICAL OPTIONS FOR THORACOLUMBAR VERTEBRAL FRACTURES

Daniele Vanni^{1,*}, Vincenzo Magliani¹ and Renato Galzio²

The surgical management of the thoraco-lumbar vertebral fractures is a difficult topic. Sometimes they can be treated conservatively, but in case of complications, such as neurological deficit or progression of the segmental kyphosis, surgical treatment becomes mandatory. Furthermore, it must be considered that some complications [1] can also occur after a correct surgical treatment, especially, in case of an osteoporotic spine. Osteoporotic vertebral injuries are divided into several types [2,3]: A) wedge-type compression fracture exhibiting progressive kyphosis, B) flat-type fracture with osteonecrosis or pseudarthrosis often exhibiting intravertebral cleft formation; C) concave or H-shaped fracture associated with anterior spur or sclerotic changes.

The best results can be found in patients treated for wedge-type lesions. The presence of an anterior bone spur in H-shaped fractures may help to stabilize the collapsed vertebra. Therefore, a posterior approach must be performed in the cases of the concave fracture or H-shaped fracture. An anterior procedure might invalidate the stabilization produced by the bone spur. Moreover, in cases of flat-type lesions, the eggshell procedure is an excellent option. [4, 5, 6].

On the contrary, the anterior surgical approaches are performed to decompress the spinal canal and to release the posterior structures, especially in the case of a severe segmental kyphosis. However, the anterior instrumentation is associated with a high rate of failure when it is used alone [7, 8, 9, 10, 11, 12]. Therefore, a combined anterior and posterior procedure may maximize the chances for a successful fusion. However, a simple augmentation of the vertebral body, if possible, represents the easiest mode to obtain the reconstruction of the

* Corresponding Author’s Email: danielevannimd@libero.it.

anterior column.[13-14]. Anterior approach is not at all easy to perform, especially in elderly patients, due to their comorbidities [8, 9]. Therefore, posterior approach is the best choice in order to obtain decompression of the neural elements, fixation of the vertebral column and correction of the deformity [11, 15, 16].

Fixation failure and loss of correction are two most fearful complications, especially in osteoporotic spine[11]. For these reasons it is necessary to obtain very stable constructs.

The problem of each instrumentation is the difference between the hardness of the osteoporotic bone and the stiffness of the implant. The pedicle screws may damage the bone, causing a screw loosening, while the cages may penetrate into the vertebral body.

In case of anterior approach, in osteoporotic spine, it is mandatory to avoid collapse of the bone graft or subsidence of the cage during the procedure of correction of the deformity, especially in postoperative period. In fact, progression of segmental kyphosis requires a combined anterior and posterior procedure.

In case of posterior instrumentation, it is mandatory to perform a stabilization involving at least two vertebrae above and two vertebrae below the fracture. Regarding the choice of the implants, pedicle screws are the best system. Sublaminar hooks were also used in the past, but the risk of laminar fracture and migration of the hook is very high, especially in osteoporotic spine. However, sublaminar hooks (or wires) can be used together with the pedicle screws, placing them at the proximal or distal edge of the constructs.

Nevertheless, the most common complication is the cement leakage into the adjacent structures. Although the rate of symptomatic clinically leaks is low, severe complications may occur, mainly spinal cord or nerve root compression, pulmonary embolism, paraplegia or death.

When the conservative treatment is not possible and open posterior fixation become an overtreatment, a minimally invasive percutaneous approach is a good alternative [17]. The minimally invasive approach allows a tissue-sparing surgery, reduces blood loss and postoperative pain. The patients affected with osteoporotic vertebral fractures, often have multiple co-morbidities and they are subjected to multidrug medical therapy. Therefore, whenever possible, it better to use this approach. Although an accurate patient selection is necessary. The percutaneous posterior stabilization, used as internal fixation system, should be reserved for stable vertebral fractures only [18].

This technique involves, through mini-incisions, the insertion of pedicle screws with two external tubes and a targeting system. It possible to insert a connecting rod, stabilizing the upper and lower vertebrae.

NEW PERSPECTIVES FOR SCREW FIXATION

From a biomechanical point of view, the pedicle provides a strong fixation for the screws in the healthy bone. But, in osteoporotic vertebra, the trabecular and cortical bone of the pedicle can be reduced by up to 50% [18]. The instrumentation of the osteoporotic spine, especially in posterior stabilization, results in failure in 12% of cases, due to loosening of the screws [19, 20, 21, 22, 23], and poor rigidity of the bone–screw contact. The correction of failure or nonunion requires a surgical revision. Therefore, different designs and methods of augmentation of the screws should be available [24]. Various methods were developed to

increase the fixation strength of the screw in case of bone deficiency. Perforated screws with vertebroplasty augmentation, solid screws with vertebroplasty augmentation and solid screws with balloon kyphoplasty augmentation are actually used. Alternatively, it is possible to combine sublaminar hooks, wires, conical screws, iliac screws or expandable screws [25, 26], but with higher strength and higher risk [27, 28]. Brantley et al. [29] suggested that there is an interaction between increase in diameter and increase in length. Polly et al. [30] reported that increasing the length of the screw alone or increasing the diameter of the screw less than 2 mm do not improve screw stability. The depth of the screw insertion plays a significant role. Screws implanted deeper than 50% into the vertebral body or bicortical screws perforating anterior vertebral cortex can enhance the bone anchorage [31, 32]. However, the bicortical fixation was avoided because of the risk of anterior leakage. The cement augmentation is regarded as an efficient system to enhance the strength of the screw in the osteoporotic bones, transferring the bio-mechanical load anteriorly from the pedicle to the vertebral body [33]. The higher strength of screw can be obtained with the larger amount of injected cement. There could be potential problems like, risk of cement leakage and difficulty of the removal of the screw. Cook et al. [34] reported that PMMA injection through the expanded screw increased the pullout strength by 250% when compared with the non-cemented expandable screw [35]. In both the techniques, cement is injected prior to insertion of the screw. Researchers designed an expandable pedicle screw (EPS) which is able to improve screw stability without harming the pedicle, avoiding the risk of pedicle fracture and vascular or visceral injuries caused by larger or longer screws. Many biomechanical studies have demonstrated that pedicle screw fixation is highly correlated with the bone density [35]. In fact the mechanical load influences the bone tissue according to Wolff's law [36]. As a result, the density of bone surrounding the expandable portions of the EPS becomes higher. The expansion of the EPS should also improve fixation strength by allowing greater bone contact, without an increase in the insertion diameter or in the screw length. EPS enhances the strength of the fixation like the traditional method of PMMA screw augmentation [37]. In conclusion, the expandable pedicle screw is an effective, safe and easy method.

At the moment there is not a single guideline about the management of vertebral fractures, both traumatic and pathological [1,2]. Timing and the indications for the conservative treatment are not clear. In addition, the surgical criteria are also poorly defined. In the past, a conservative treatment for at least 30 days was considered as proper treatment for the majority of the fractures, especially in case of osteoporosis vertebral fractures (OVF). Surgical solutions were necessary if pain persisted-vertebroplasty for vertebral fractures with loss of height less than 30%, kyphoplasty for the ones with height loss greater than 30%. The conservative treatment avoids surgical risks. However, it forces the patient to a poor quality of life and it does not stop the domino effect, with poor results. Vertebral augmentation procedures are fast, performed in general anesthesia and percutaneously. Therefore, a standing radiography is necessary in patients with acute, severe back or low back pain and a risk profile (age >65 years, positive anamnesis for previous vertebral fractures, metabolic diseases, renal failure, and prolonged therapy with the corticosteroids or antiepileptic, body mass index <20). CT scan is performed in order to characterize the fracture personality, to obtain more detailed information about fracture type and to distinguish between a simple compression fracture from a more complex lesion. MRI shows signs of spinal cord and/or

* Corresponding Author’s Email: danielevannimd@libero.it.

dural sac compression, radicular conflict, and also allows to distinguish between new and old fractures, according to signal intensity in TSE (Turbo Spin Echo) T2 weighted sequences. This is the most important aspect according to which surgical indication and eventually the vertebral height recovery entity are established. The more recent the fracture, the greater is the possibility of recovery of height.

Percutaneous surgery with VP or KP [3] is necessary in case of persistent pain or contraindications to use of orthosis (e.g. intolerance, restrictive respiratory failure).

VP is recommended for patients with persistent pain and vertebral collapse less than 30% until 1 month after the fracture or after 3 months.

KP is indicated in case of vertebral collapse persistent pain with high body reduction equal or higher than 30%, between 1 and 3 months. [1,2].

Only PMMA administration could be used for VP, allowing vertebral body reinforcement without restoration of vertebral body height. KP provides a partial correction of vertebra body height through an "expandable balloon". KP is a more biomechanically valid process. This technique provides for the stabilization of the fracture after reduction. In addition, the creation of an intrasomatic cavity filled with PMMA reduces the risk of cement leakage. [3, 4, 5]

Although the majority of PMMA leakages are asymptomatic, adverse effects of VP include localized bleeding, infection, mediastinitis, pain, neurological symptoms (neuropathic pain and paraplegia) and pulmonary embolism following leakage of injected material [6, 7, 8, 9, 10].

PMMA leakage has been reported into the venous plexus, inferior vena cava, the epidural space in the spinal canal, neural foramina, intravertebral disk space, and paraspinal soft tissue. Adjacent vertebral fracture is a possible complication, due to a major cement stiffness compared to the vertebrae one. (Fribourg et al. 2004). PMMA is contraindicated during infections. Hypotensive reactions may occur between 10 to 165 seconds from bone cement application. They could last from 30 seconds to 5 minutes or more, inducing cardiac arrest.

Percutaneous vertebral augmentation procedures (PVAP) are based on the cement injection into the vertebral body. These techniques have achieved great success in recent years as they allow an efficient OVF management; stabilizing the vertebra, especially the anterior column. they also ensure a rapid pain resolution. The pain in fact, is due to micro-motion fragments at the fracture site. Treatment of OVF has been radically changed in the last three decades. The first generation mini-invasive surgery for treatment of VCF - vertebral compression fracture by percutaneous injection of bone cement (PMMA) was described by Galibert et al. in 1987; this surgical procedure goes by the name of vertebroplasty. [5] This technique produced excellent results in terms of pain relief. However, unfortunately, it appears incomplete in several aspects. In fact, the vertebroplasty does not allow recovery of vertebral body height. Therefore, vertebral body remains collapsed and so the spinal biomechanic is altered. There is not possibility to stop the domino effect. Additionally, it is necessary to inject a very low viscosity and high pressure cement, with risk of leakage of around 30%. These problems led to the creation of second-generation PVAP. The balloon kyphoplasty [5] is a recent change to percutaneous vertebroplasty, conducted for the first time by Reiley in 1998; this procedure involves the inflation of a balloon catheter in the collapsed vertebral body to restore its height before the stabilization with bone cement. The use of the balloon can create a cavity inside the vertebral body; in this way, the cement can be injected with less pressure and greater viscosity, considerably reducing the risk of leakage. [11-16] Reducing the relevance of cement as the primary stabilizer in vertebral compression fractures

may reduce or eliminate concerns about cement leakage.[17,18] Unfortunately, recovery of vertebral body height is temporary. In fact, as soon as the balloon is deflated, there is often a new total or partial vertebral body collapse.[19-22] This has led to creation of a new device. They obtain recovery of vertebral height. However, they must not be removed from the vertebral body to allow the injection of PMMA. Therefore, the conventional balloon can be replaced by equivalent mechanical systems:[23,24] third generation PVAP.

There are different systems and devices available for PVAP, with similar characteristics, although they are different for many features :

Spine Jack® [1] [Figure 1] is a new device for mechanical kyphoplasty. It is a titanium implant designed to restore vertebral height through a distraction effect via bilateral transpedicular minimally invasive approach, the device is inserted into the vertebral body (from T10 to L5) [Figure 2] and gradually expanded like a little jack [Figure 3] [2] . The distraction exerted by the device allows fracture reduction that occurs by ligamentotaxis on the anterior longitudinal ligament. Spine Jack® is equipped with a mechanical and not a hydraulic opening; this ensures a gradual and controlled vertebral fracture reduction. This feature allows to recover the collapsed vertebra and to provide the primary support 3D to the structure in order to mechanically stabilize the vertebrae in axial compression [3]. Once this step has been completed, bone cement is injected into the restored vertebra in order to secure the vertebral structure, and relieve the patient’s pain. The presence of two symmetrical devices into the vertebral body allows also a polymethylmethacrylate (PMMA) homogeneous spreading. The expansion of the device creates a high-viscosity cement preferential flow direction, also reducing the risk of leakage . When injected, cement inter-digitation creates a large contact area below the midline: This helps to provide stability to the obtained vertebral body reduction. Although, the technique was developed for osteoporotic fractures, it could be used in traumatic fractures of the thoracolumbar vertebrae.

Figure 2. Spine Jack® insertion (From: Vanni et al. [3] J Craniovert Jun Spine 2012).

Figure 3. Spine Jack® opening (From: Vanni et al. [3] J Craniovert Jun Spine 2012).

OsseoFix Spinal Fracture Reduction System® [Figure 4,5]: It is intended for the minimally invasive percutaneous treatment of vertebral fractures in the region T10-L5 due to

osteoporotic collapse [4]; it facilitates the correction/reduction of OVF using a titanium implant with PMMA cement [4,5]. The cylindrical titanium implants, once inserted into the vertebral body, restores the height of the vertebral body in question and immediately stabilize a vertebral fracture; the space created by the installation of titanium stent in the vertebral body (which remains in situ) is filled with PMMA [4,5,6].

VBS-Vertebral Body Stenting System® [Figure 6,7]: The VBS is a titanium device, intended for the reduction of painful vertebral compression fractures and/or creation of a void in cancellous bone in the spine for the treatment of levels ranging from Th5-L5 [7,8]. It is intended to be used in combination with a legally-marketed PMMA based bone cement adequately indicated for use in vertebroplasty or kyphoplasty procedures [9,10]. The VBS stents are introduced percutaneously into the vertebral body with only a stab incision required to place the access instruments. Expanding the VBS stents inside the collapsed vertebra offers height restoration and conservation. The mechanical construct restores the height while at the same time offering a cavity for injection of highly viscous PMMA[11, 12, 13].

It is possible to affirm that, although the different devices have the same purposes of usage, they have technical characteristics that make them different one from each other. Therefore, it is appropriate to evaluate them in detail, in order to understand how to use them to the properly[14, 15]. In other words, we can say that, depending on different parameters, including the etiopathogenesis of the fracture, its morphological characteristics and the age of the patient, it may be more correct to use one specific device rather than another[16, 17]. Considering different experiences of several surgeons, we will discuss in detail the various devices, rationality of their use and we will try to draw a guide line of treatment that could help to choice the more proper and appropriate device for the particular type of vertebral fracture [14, 15, 16, 17].

VBS: EVALUATION AND INDICATIONS

Daniele Vanni^{1,*}, MD and Vincenzo Magliani², MD

Symptomatic vertebral compression fracture can negatively impact health and quality of life by causing substantial pain and severe disability [1, 2]. These vertebral fractures may result from trauma but they can be also incidental to osteoporosis or tumors. In the latter case, they usually represent a secondary localization of tumor disease [3, 4]. Regardless of the cause, restoration of height and realignment of the vertebral bodies are mandatory in order to prevent the progression of the deformity and the commensurate deterioration of quality of life [1, 2, 3, 4]. Vertebral Body Stenting (V.B.S.) is a specific third generation intrasomatic expandible device for percutaneous vertebral augmentation. It represents an available option to alleviate pain but especially to restore the height of the fractured vertebra, as well as the normal curvature of the spine [5]. This aspect is important in order to prevent postural abnormalities and pain caused by pathological progressive kyphosis. In 1958, the AO formulated four basic principles, which have become the guidelines for internal fixation. They can be summarized in: 1) anatomic reduction of the fracture 2) immediate and effective primary stability 3) preservation of blood supply and 4) Early and active mobilization [6]. At the beginning, these criteria had been established for the treatment of long bones fractures, but fundamental aims of fracture treatment in the limbs and fusion of the spine are the same. In particular, the specific goal of spine treatment is to restore as much function as possible to the injured neural elements. Therefore, the AO principles, modified for the vertebral fractures [7, 8] surgical treatment are [9]: - anatomical reduction: reinstatement of spine alignment improves spine biomechanics. It allows the vertebral column to perform properly its protective function and it is responsible for the clinical improvement and reduction of pain. - stable internal fixation: it allows to maintain not only the integrity of the spinal functional

* Corresponding Author’s Email: danielevannimd@libero.it.

unit, but also it provides the balance and the physiologic three-dimensional form of the spine.

- preservation of blood supply: an ideal surgical technique for treatment of vertebral fractures, should be able to minimize the damage of anatomical structures and to reduce the disturbance of nerve roots and dura. It should be the as atraumatic as possible, trying not to compromise the vascular supply.
- early and active mobilization: restoration of normal spinal anatomy allows immediate pain reduction and early patient mobilization. It is possible only if stable spine is achieved.

VBS [10, 11] enables a minimally invasive surgical treatment of vertebral fractures, fully satisfying these four fundamental principles. In fact VBS [Figure 1] is introduced percutaneously into the vertebral body with only a stab incision required to place the access instruments. The system is made of titanium and it works like a real stent. In fact, using a balloon (the same that was employed to perform the classic kyphoplasty), the device is expanded inside the vertebral body, ensuring, by ligamentotaxis, an "effective reduction", restoring the correct vertebral morphology and allowing restoration and conservation of height of vertebral body while at the same time offering a cavity for injection of highly viscous PMMA based bone cement [Figure 2] [12, 13]. VBS offers an expansion ratio of 400%: this is fundamental for reconstruction of collapsed vertebral body. After the expansion phase, the balloon can be deflated and definitively removed, without the risk of loss of reduction, since the device is crushproof and it remains into the vertebral body, overcoming the problem of partial height loss after removal of the balloon. The cavity, obtained through the device expansion, is then filled with PMMA based bone cement, providing additional primary stability.

VBS is intended for the reduction of painful vertebral compression fractures and/or creation of a void in cancellous bone in the spine for the treatment of levels ranging from Th5-L5 [Figure 3, 4, 5, 6] [12, 13, 14].

Figure 1. Vertebral Body Stenting: implant.

Figure 2. Vertebral Body Stenting: PMMA injection.

Figure 3. Vertebral fractures: Rx imaging.

The indications are: - osteoporotic vertebral compression fractures from Th10-L5 without involvement of the posterior vertebral edge classified after Genant, Grade 2 and Grade 3 with a kyphotic angulation of more than 15° [15, 16]. ; - fractures without the involvement of the posterior vertebral edge, classified according to AO classification in [7, 8, 9]:

A1.1 Endplate impaction

A1.2 Wedge impaction fracture

A1.3 Vertebral body collapse

A3.1 Incomplete burst fracture; (depending on the degree of posterior wall involvement, internal fixation must be used in addition)

– In combination with internal fixation

A3.1 Incomplete burst fracture

A3.2 Burst-split fracture; in these cases the extent of the gap width should not be too wide

B1.2 Posterior disruption predominantly ligamentous associated with type A fracture of the vertebral body

B2.3 Posterior disruption predominantly osseous with type A fracture of the vertebral body

The contraindications are: fractures that need internal fixation: (A2 split fractures, A3.3 complete burst fracture, B1.1 posterior disruption predominantly ligamentous with transverse disruption of the disc, B2.1 transverse bicolmn fracture, B2.2 posterior disruption predominantly osseous with disruption of the disc, B3 anterior disruption through the disc and all C types. Extensive mechanical and biomechanical testing has been performed to characterize the mechanical behavior and performance of the VBS [17]. The preclinical testing of the VBS was designed to evaluate all relevant loading conditions that may impact the device to demonstrate a reasonable assurance of safety. These biomechanical tests demonstrated a significant decrease of height loss after balloon deflation using VBS compared to balloon kyphoplasty. For instance, VBS was able to significantly maintain the pre-fracture height and avoid a loss of reduction which has been measured with balloon deflation in kyphoplasty. If compared with balloon kyphoplasty, it has been demonstrated that VBS showed positive clinical results allowing to obtain a significant level of pain relief and functional improvement.

Figure 4. Vertebral fractures: 3D TC imaging.

Figure 5. Vertebral fractures: Post-op control.

Figure 6. Vertebral fractures: Post-op control.

VAS and ODI score were reduced by 6.4 points and 41.7% respectively at 12 months. In addition, a substantial improvement of the vertebral body height to 15.3% at 12 months was also demonstrated, as well as a good kyphosis correction to 4.5° at 12 months [Figure 7]. Risk of adjacent vertebral fracture was estimated to be 9%, which seems similar or somewhat lower than the rates reported in the literature for balloon kyphoplasty. VBS could be considered to be a safe and effective surgical technique to treat vertebral fractures and osteoporotic vertebral compression fractures with a low rate of adverse effects. The proper

atraumatic technique enables minimal retraction or disturbance of the nerve roots and dura, and maintains the stability of the facet joints. The ideal surgical technique and implant design minimize damage to anatomical structures, i.e., facet capsules. keeps the soft tissue attachment intact, and creates a physiological environment that facilitates healing. This specific treatment usually leads to an immediate pain relieve and allows for an early mobilisation and return to normal activity [18, 19].

At the moment there is no single guideline for management of osteoporosis vertebral fractures (OVF) [1,2]. Timing and the indications for the conservative treatment are not clear; The surgical criteria are also poorly defined. In the past, a conservative treatment for at least 30 days was considered the proper treatment for the majority of the fractures. If the pain persisted, a surgical solution was needed: Vertebroplasty is for OVF with loss of height less than 30%, while kyphoplasty is for OVF with loss of height greater than 30%. The conservative treatment avoids surgical risks. However, it forces the patient to a poor quality life and it does not stop the domino effect, causing poor results. Vertebral augmentation procedures are fast, performed in general anesthesia and percutaneously. Therefore, a standing radiography is necessary in patients with acute, severe back or low back pain and a risk profile (age >65 years, positive anamnesis for previous vertebral fractures, metabolic diseases, renal failure, and prolonged therapy with the corticosteroids or antiepileptic, body mass index <20). CT scan is performed in order to characterize the fracture personality, in order to obtain more detailed information about fracture type and to distinguish between a simple compression fracture from a more complex lesion. MRI shows signs of spinal cord and/or dural sac compression, radicular conflict, and also allows to distinguish between new

* Corresponding Author’s Email: danielevannimd@libero.it.

and previous fractures, according to signal intensity in TSE (Turbo Spin Echo) T2 weighted sequences. This is the most important aspect according to which surgical indication and eventually the recovery of vertebral height entity are established. The more recent the fracture, the greater is the possibility of height recovery. Percutaneous vertebral augmentation procedures (PVAP) are based on the cement injection into the vertebral body. These techniques achieved great success in recent years as they allow an efficient OVF management; by stabilizing the vertebra, especially the anterior column, they ensure a rapid pain resolution. The pain in fact, is due to micro-motion between the fragments at fracture site. Treatment of OVF has radically changed in the last three decades. The first generation mini-invasive surgery for treatment of VCF - vertebral compression fracture by percutaneous injection of bone cement (PMMA) was described by Galibert et al. in 1987; this surgical procedure goes by the name of vertebroplasty.[3] This technique produced excellent results in terms of pain relief. However, unfortunately, it appears incomplete in several aspects. In fact, the vertebroplasty does not allow any recovery of vertebral body height . Therefore, vertebral body remains collapsed and so the spinal biomechanics is altered There is no possibility to stop the domino effect. Additionally, it is necessary to inject a very low viscosity and high pressure cement, with a risk of leakage of around 30%. These problems led to the creation of second-generation PVAP. The balloon kyphoplasty [4] is a recent change to percutaneous vertebroplasty, conducted for the first time by Reiley in 1998; this procedure involves the inflation of a balloon catheter in the collapsed vertebral body to restore its height before the stabilization with bone cement. The use of the balloon can create a cavity inside the vertebral body. In this way, the cement can be injected with less pressure and greater viscosity, considerably reducing the risk of leakage.[5-10] Reducing the relevance of cement as the primary stabilizer in vertebral compression fractures may reduce or eliminate concerns about cement leakage.[11-17] Unfortunately, recovery of height recovery is. In fact, as soon as the balloon is deflated, there is often a new total or partial vertebral body collapse.[18-21] This has led to research for creation of new devices. They allow recovery of the vertebral height. However, they must not be removed from the vertebral body to allow the cementing. Therefore, the conventional balloon can be replaced by equivalent mechanical systems:[22,23] Third generation PVAP.

Figure 1. Spine Jack System®.

Figure 2. Spine Jack® insertion.

Figure 3. Spine Jack® opening.

Spine Jack® [23,24] [Figure 1] is a new device for mechanical kyphoplasty. It is a titanium implant designed to restore vertebral height through a distraction effect via bilateral transpedicular minimally invasive approach, the device is inserted into the vertebral body (from T10 to L5) [Figure 2] and gradually expanded like a little jack [Figure 3]. The distraction exerted by the device allows fracture reduction that occurs by ligamentotaxis on the anterior longitudinal ligament. Spine Jack® is equipped with a mechanical rather than a hydraulic opening; this ensures a gradual and controlled reduction of vertebral fracture. This feature allows to recover the collapsed vertebra and to provide the primary support to the structure in order to mechanically stabilize the vertebrae in axial compression. Once this step has been completed, bone cement is injected into the restored vertebra in order to secure the vertebral structure, and relieve the pain. The presence of two symmetrical devices into the vertebral body also allows a homogeneous spreading of polymethylmethacrylate (PMMA). Expansion of the device creates a preferential flow direction of high-viscosity cement, also reducing the risk of leakage. When injected, cement inter-digitation creates a large contact area below the midline: This helps to add stability to the obtained vertebral body reduction.

Although, the technique was developed for osteoporotic fractures, it could be used in traumatic fractures of the thoracolumbar vertebrae.

This technique allows a good reconstruction of the anterior column, restoring vertebral height. Another feature to highlight is the advantage of preventing cement leak into intervertebral disc space, which could increase the risk of adjacent vertebral body fractures in OVF. In fact, the device has a security system: If the load forces concentrated on the devices are too high, the system automatically blocks itself; a further expansion of the device does not occur, thus reducing the risk of breakage of vertebral endplates. Furthermore, an excellent reduction of superior endplate may have the potential benefit of better future performance of injured disc.

Figure 4. Vertebral fracture in patient with osteoporosis.

Vanni et al. showed that Spine Jack® represents a safe and effective system for treatment of OVF. In this study, Spine Jack® and kyphoplasty were compared, creating two groups of evaluation. Spine Jack® and kyphoplasty groups did not differ significantly in age, gender distribution, location of OVF, duration between injury and surgery, pre-operative VAS pain score, vertebral body height, or kyphotic wedge angle [Figure 4 and 5]. The degree of anterior column injury is best assessed using the McCormack and Gaines load sharing classification. The safe indication would be at 3 points and limited to approximately 4-5 points. Patients underwent a clinical follow-up (using VAS and Oswestry disability index [ODI]) and post-operative standing plain radiogram of the spine at 1, 6, and 12 months. The radiographic parameters taken into account were: Post-operative anterior vertebral body height, preoperative anterior vertebral body height, cephalic anterior vertebral body height, and caudal anterior vertebral body height. The fractured vertebral body height restoration was calculated according to the following equation: $2 \times (\text{post-operative anterior vertebral body height} - \text{pre-operative anterior vertebral body height}) / (\text{cephalic anterior vertebral body height} + \text{caudal anterior vertebral body height}) \times 100\%$. [25] Vertebral height was measured immediately before and after PVAP, in order to assess restoration of vertebral height.

Figure 5. Pre-operative nuclear magnetic resonance.

Figure 6. Final intra-operative control.

A semi-quantitative assessment of recovery of vertebral height was performed and three assessment degrees were identified: Grade 0 (no change), grade 1 (below 50%) and grade 2 (greater than 50%). Compared to the Spine Jack® group, the kyphoplasty group required a little longer operation time (an average of 40 min vs. 45 min, $P < 0.05$), and a greater amount of PMMA (4.0 vs. 5.0 mL, $P < 0.05$). The post-operative increase in vertebral body height was greater in the Spine Jack® group than in the kyphoplasty group ($P < 0.05$). The 85% of the patients who underwent PVAP using the Spine Jack® system has returned to the assessment degree 2 [Figures 6 and 7], 12% in 1 and 3% in 0. The 58% of the patients who underwent PVAP using balloon kyphoplasty returned to the assessment degree 2, 26% in 1 and 16% in 0. There was no statistical difference in VAS pain scores and in the ODI between the treatment groups at any stages from the pre-operative period, through the post-operative period, to the final follow-up. In group A, there were not leakage events, nor device loosening. In the group B, there were 20 but not clinically significant leakage events. In both

groups, there was no iatrogenic vertebral endplates fractures or fractures of the vertebra above or below. Neurological defects, radicular symptoms, and pulmonary embolism have never occurred.

Figure 7. Final intra-operative control.

Finally, it is mandatory to highlight that Spine Jack® is useful not only for treatment of OVF, but also in case of vertebral fractures, although they could be not recent. In fact the the device is able to perform a significant force of elevation, and also able to reduce not very “fresh” fractures. Only the third generation device for PVAP able to treat this type of fractures.

Figure 8. Radiographic post-operative control.

In conclusion, it is possible to affirm that Spine Jack® is able to determine a safe restoration of vertebral body height, if compared to the conventional balloon kyphoplasty. This is due to the efficient mechanical characteristic of Spine Jack® system, and above all, it is due to the possibility of leaving the devices into the vertebral body. This avoids vertebral body recollapsing before cement injection. [Figure 8]. Spine Jack® has the advantage to restore, according to the “fracture freshness,” the vertebral height and the normal spine

biomechanic and stability. The restoration of normal spine biomechanics results in an interruption of the domino effect and in a reduction of the risk of new vertebral fractures. [26].

INTRODUCTION

Vertebral compression fractures represent one of the most common complications of osteoporosis. In western countries the prevalence of vertebral compression fractures is constantly increasing because of aging population. Consequently the morbidity and mortality burden related to their effects, mainly represented by pain and kyphotic deformities, is also increasing. This leads to deep social and economical costs.[1]. Vertebral augmentation of acute collapses is a minimally invasive treatment option with proved effectiveness in reducing pain and improving quality of life of the affected patients whose symptoms were refractory to medical treatment [2, 3, 4, 5]. Since its introduction in medical practice in the nineties for the treatment of aggressive vertebral angioma, vertebral augmentation with polymethyl-methacrylate (PMMA), till today the most widely employed filler material, has evolved rapidly. Currently it is considered an effective option also for the treatment of osteoporotic and non-osteoporotic collapses, with reported success rates of 80-95% and 70-92% respectively [6, 7, 8]. In the late nineties kyphoplasty was introduced as an alternative procedure to traditional vertebroplasty with the speculated advantage of reduction of kyphotic deformities owing to the creation of a cavity inside the vertebral body then filled with PMMA [9, 10]. Although is still a matter of debate which procedure, traditional vertebroplasty over kyphoplasty, bear the best absolute advantage in pain improvement, both them share some rare complications. Some complications, like cement leakage/embolism, are mainly related to the procedure itself, while other, as thermal/chemical/mechanical injuries, are mainly related

* Corresponding Author's Email: grillea@hotmail.com.

to the polymerization characteristics of the PMMA and to its intrinsic high stiffness [11, 12, 13]

Vertebroplasty and kyphoplasty can be considered safe procedures if properly performed by skilled and prudent operators, and their risks can be considered acceptable if the right indications are met [13]. Several efforts have been made to further decrease the occurrence of these complications. In recent years some companies have focused on the development of non-toxic resorbable cements, while other on the development of devices able to control or reduce cement spread inside the vertebral body, like curved injection needles or expandable containers. [14, 15, 16]

DEVICE CHARACTERISTICS AND INDICATIONS

Recently a new expandable titanium device, OsseoFix® (AlphaTec Spine Inc. Carlsbad CA), has been developed for treatment of osteoporotic vertebral compression fractures. It is composed of a titanium mesh that, once implanted bilaterally inside the vertebral body through both pedicles, is expanded with the aims of decreasing the kyphotic deformity, stabilizing the collapse compacting the surrounding trabecular bone and reducing the amount of cement required with the potential following risk of leakages through any way.

OsseoFix® implant is intended for use inside vertebral bodies from level T6 through level L5. It is available in three measures according to the width of the pedicles involved. OsseoFix® implantation is usually indicated in patient with painful stable vertebral fractures type A1.1 to A1.3 or A3.1, according to AO classification, dating at least three weeks and refractory to conservative treatment, in which intravertebral edema is evident on magnetic resonance imaging (MRI), i.e., bone hypointensity on T1 weighted images and/or equivalent hyperintensity on T2 weighted fat saturated images. Other two remarkable cases in which OsseoFix® is indicated, which represent an extension of the usual indications typical of traditional vertebroplasty, are represented by acute stable traumatic vertebral collapses of the above mentioned type occurred in young patients and vertebral collapses secondary to osteoporosis dating back more than three weeks and up to 9 months, also known as “inveterate” collapses, in which signs of bone marrow edema are still detected on MRI.

The contraindications do not differ from the standard ones working for traditional vertebroplasty. The main contraindications are the following: vertebral compression fracture with evidence of retropulsed fragment impinging dura mater or spinal cord; previous treatment at the same level; ongoing systemic or local infections; history of severe anaphylactic reactions to iodine based compounds; body mass index over 30; known illnesses such cancer; irreversible coagulopathies; pre-existing calcium disorders; renal failure; psychiatric disorders of any kind.

TECHNIQUE AND DISCUSSION

OsseoFix® deployment does not significantly differ from the deployment of any other expandable intravertebral device. Here we report what we do at our Institution; all the phases of the procedure are guided by fluoroscopy. The patient lie prone over the fluoroscopic table

under local anesthesia and mild sedation. We usually use only mild sedation, unless the anesthetist believe the clinical conditions of the patient require general anesthesia, a very rare occurrence. All the following steps are performed bilaterally on each peduncle. Once the skin over the involved level is prepped in a sterile fashion, several mL of lidocaine are injected subcutaneous in order to accomplish local anesthesia. Under fluoroscopic guidance two 22 G spinal needles are then inserted down to the posterior elements of the vertebral body and periosteal local anesthesia is accomplished injecting several mL of naropine. The OsseoFix® Spine Fracture Reduction System is composed of a tunneling cannula, whose diameter fit with that of the device chosen varying from 10G to 13G, that is introduced inside the pedicle up to its junction with the vertebral body, with the aim to create a working channel through the pedicle. The stylet of the working cannula is then retracted and a kirschner wire is introduced inside the vertebral body. Coaxially to the working cannula and over the kirschner wire a tapper is introduced up to the anterior wall of the vertebral body. The tapper, with diameter varying according to the device chosen, must be screwed while advancing it in order to create a channel in which the device will be fitted. The tapper is then changed with the device that is coaxially introduced and advanced inside the vertebral body targeting its tip to the anterior third of the vertebral body itself. Once on the fluoroscopy checks the position is considered correct the operator expand the device acting on the screw handle. The device is lodged at the tip of the introducer and is locked between two vise-like ends that approximate each other acting on the screw handle. The approximation of the ends shortens the device that is so forced to expand. The shortening and expansion range vary with the measure of the device chosen, as shown in Figure 1. This operation leaves little room to the operator discretion, thus providing a guarantee for controllability and reproducibility (Figure 2).

Figure 1. Drawing A shows the working cannula inside the pedicle with the tip up to the pedicle/vertebral body junction. Drawing B shows the OsseoFix unexpanded implant in correct position with the tip at the anterior third of the vertebral body. Drawing C shows both the implant expanded before cement injection. Drawing D shows both the implants injected with cement; the detail on the left shows the interdigitations of cement and trabecular bone through the cells of the titanium mesh.

The cavity created following the expansion of the device is stable because, in contrast with kyphoplasty or other balloon assisted stentoplasty, the expanded device remains in place stabilizing the cavity itself. There are some reports about the use of this device with in vitro specimen without injection of any cement at all [17]. In these cases no significant difference in strength and stiffness was found between the specimens with and without cement injected, leading to a speculated remarkable advantage of lack of complications related to the cement injection. However these were only in vitro findings that necessitate further study but that look promising.

The surrounding collapsed trabecular bone is compacted outward during device expansion and some of it is squeezed through the cells of the titanium mesh. A double advantage follows this operation, on one side the compaction of the trabecular bone lead to an increase of the vertebral body height, hence reducing kyphotic deformity, and on the other side the interdigitation of trabecular bone occurring through the cells of the mesh stabilize the device in place. At the end of the expansion PMMA cement is injected inside the expanded device. The cement employed with the device is composed of 95%wt PMMA and 5%wt hydroxyapatite (HA). The HA promote the biocompatibility of the cement. The overall volume of PMMA is significantly reduced compared to the amount required by traditional kyphoplasty, only about 1 mL for each device suffices. Also the cement interdigitates through the cells of the titanium mesh further stabilizing the device (Figure 3). The compacted trabecular bone surrounding the device decrease the number and width of that small bone channels through which cement can leaks, that is another remarkable advantage.

Figure 2. (Continued).

Figure 2. Intraoperative fluoroscopic views showing the kirschner wire in place (A), the unexpanded device in place (B), the device expanded before cement injection (C), both devices in place at the end of the cement injection (D) and two end-procedure latero-lateral and antero-posterior views showing both devices in place correctly positioned and filled with cement (E).

At our Institution we are using OsseoFix® Spine Fracture Reduction System since 2011. Up to the time we are writing more than 120 patients have undergone the implantation with over 200 overall levels treated. In many cases the procedure was accomplished on two or more consecutive levels and in a few cases there were two or more levels treated with a healthy vertebra in between (sandwich). All procedures have been accomplished successfully without any complication both during and after the procedure. The follow-up interval is over one year for most of these patients.

Figure 3. Picture A shows the device expanded and filled with cement removed from an in vitro specimen with evidence of interdigitation of trabecular bone and cement through the cells of the titanium mesh. Picture B shows another similar specimen dissected on its major axis in which such interdigitations are well rendered.

We found in all cases a significant and stable improvement of pain that, like traditional vertebroplasty, is almost always immediate. The reduction of kyphotic deformities has also been found significant in all cases, particularly in patients with multiple levels treated. In no case there have been adjacent fractures, finding particularly remarkable in cases of double level treated with healthy sandwich vertebral bodies in between. Failure of the device has not occurred in any case.

CONCLUSION

OsseoFix® Spine Fracture Reduction System provide both immediate and long term effectiveness in reducing pain and kyphotic deformities secondary to vertebral compression fractures. It is a new device that bears in it several advantages over the traditional kyphoplasty and vertebroplasty, mainly the consistence of the increase of vertebral body height and the almost absent risk of cement leakages through any way.

Although some differences could exist among the various devices, for example, the dimension and the diameter of the device or the amount of PMMA that could be used, surgical technique is the same for all the third generation systems. The different steps, that are mandatory, take place from the patient evaluation, pre-operative planning, patient position, recruitment of anatomical landmarks, surgical access, introduction of the device and expansion before PMMA injection [1, 2].

PATIENT ASSESSMENT

Before surgery, it is mandatory to dispose of [2, 3, 4, 5]:

- Current X-ray images, in standing position, of the thoracic and lumbar spine, in two planes, in order to assess the fracture and the spinal alignment;
- A spiral CT and MRI scan of the painful region of the spine;
- If an MRI scan is contraindicated, a bone scan may identify an acute fracture;
- Ruling out another cause of pain;
- Feasibility of surgery and use of anaesthesia.

* Corresponding Author’s Email: danielevannimd@libero.it.

PLANNING OF STENT PLACEMENT

The placement of the stents should be planned based on the AP image which gives hints for the route of insertion [6, 7, 8].

PRE-PLANNING OF STENT SIZE

The stent size for the procedure can roughly be planned preoperatively by CT scan [9].

INTRAOPERATIVE X-RAY IMAGING

The device must be implanted using X-ray on both planes, using two C-arms, or with one freely mobile C-arm [10].

ANATOMICAL LANDMARKS

For percutaneous vertebral augmentation procedures, two stents per vertebra should be placed in a symmetrical, paramedian position within the affected vertebral body to achieve optimum reduction of the spinal fracture without damaging the lateral vertebral body edges. Ideally, the distance from the compressed endplate to the stents should be about 5 mm [Figure 1] [11, 12].

Figure 1.

The position of the stents needs to be planned evaluating pre-operative images. The following landmarks have to be defined on the spine [13, 14, 15]:

- Both pedicles
- Spinous process
- Endplates
- Posterior wall of vertebral body

PATIENT POSITIONING

The patient must be placed in prone position on a lumbar support. The table must be radiolucent in both planes [Figure 2, 3].

Figure 2.

Figure 3.

The table should allow free manipulation of the C-arm over the operative site in both planes [Figure 4].

Figure 4.

ACCESS OPTIONS

There are two access options to the targeted vertebral body, depending on its anatomy [16, 17, 18, 19]:

1. Transpedicular access

As a general rule, the bilateral skin incisions for the transpedicular approach are 1–2 cm lateral and up to 1 cm cranial to the centre of the pedicle [Figure 5]. It is also important to remember that this entry point could slightly change in case of obese patient, or in case of very tall or very short people [20, 21] .

2. Extra-/Parapedicular access

The bilateral skin incisions for the extra-/parapedicular technique are planned according to the anatomical situation [Figure 6]. In patients with small pedicles, especially in the higher thoracic spine, an extrapedicular approach is preferable [22, 23] .

Figure 5.

Figure 6.

INSTRUMENT POSITIONING WITH A GUIDE WIRES

First the guide wires are positioned. The other instrumentation follows the path created by the guide wires. Once the anatomical landmarks are detected, the guide wires can be percutaneously introduced through skin incisions using X-ray control (AP and lateral).

Either a transpedicular or extra-/parapedicular access may be selected depending on the anatomy of the vertebral body to be treated [24].

Note: With either access technique it is important to place the two devices symmetrically towards the midline and the anterior wall of the vertebral body at a medial location. In this

position the devices have room to expand without pressing against either the lateral wall, or the other device [Figure 7] .

Figure 7.

TRANSPEDICULAR ACCESS

Position Guide Wires

Under AP and lateral X-ray control the guide wires must be inserted to the superior outer pedicle quadrant using slight manual pressure. Once the guide wires touch the bone the outlines of the lateral pedicle are reached. Both guidewires are driven with controlled blows from a hammer through the cortex [25, 26]. Cautiously the guide wires are advanced into the center of the vertebral body. It is very important to highlight that the tips of the guide wires should be about and not closer than 5 mm to the anterior wall of the vertebral body.

Figure 8.

Figure 9.

They should be positioned symmetrically and aligned in both AP and lateral views [Figure 8, 9] [27]. The tips of the guide wires must not pass the midline in AP view until they have passed the posterior wall in the lateral view. When the guide wires are advanced, it is important to ensure that they are not inserted too far medially, in order to avoid penetration into the spinal canal. It is also essential to avoid overdrive the guide wires into vascular structures beyond the anterior cortical wall [28] .

Position Working Sleeves over Guide Wires

The instrument assembly of working sleeve, side-opening cannula and cannulated trocar is used. The instrument assembly is pushed with a counterclockwise turning motion over the first guide wire.

It is mandatory not to insert the working sleeve into the bone without the side-opening cannula. This could damage the working sleeve and obstruct stent insertion. Do not hammer on the side-opening cannula, cannulated trocar and working sleeve. The working sleeve can also be placed without the mounted cannulated trocar (working sleeve with side-opening cannula over guide wire). If this method is chosen, there is more clearance between the diameter of the guide wire and the side-opening cannula to allow for minor correction in the trajectory when positioning the working sleeve. This can lead to a slight resistance while penetrating the bony vertebral body surface [29]

Placement working sleeve must be evaluated under lateral X-ray control. It is mandatory to ensure that the tip of the working sleeve has passed the pedicle and is positioned inside the vertebral body.

When the working sleeve is inserted, the position of the guide wire must be monitored in order to confirm that it is not advancing forward. It is possible to pull back the side-opening

cannula to verify the positioning of the working sleeve. All this procedure must be repeated on the contralateral side. Once both working sleeves are in place, the side-opening cannulae with the inserted cannulated trocar and the guide wires can be removed [30].

The working sleeves remain in the vertebral body. It is important to advance the instrument assembly carefully in order to avoid any injury to the physician's hand. Since the guide wire is longer than the combined length of the pre-mounted working sleeve with the side-opening cannula with cannulated trocar, it will protrude through the handle of the side-opening cannula.

EXTRA-/PARAPEDICULAR ACCESS

Position Guide Wires

Guide wires are inserted using slight manual pressure under AP and lateral X-ray control.

Both the guide wires is inserted up to the vertebral body and they are driven with controlled blows from a hammer through the cortex. Should you touch bone before reaching the vertebral body, the outline of the lateral pedicle has been reached [Figure 10]. The guide wires must be cautiously advanced and, if it is necessary, it must be redirected in order to reach the center of the vertebral body [31]. The tips of the guide wires should be about and not closer than 5 mm to the anterior wall of the vertebral body.

The tips of the guide wires must not pass the midline in AP view until they have passed the posterior wall in the lateral view. When advancing the guide wires, it is mandatory to ensure that they are not inserted too far medially, to avoid penetration into the spinal canal. It is also essential to avoid overdriving the guide wires into vascular structures beyond the anterior cortical wall [32].

Figure 10.

Positioning Working Sleeves over Guide Wires

The instrument assembly of working sleeve, side-opening cannula and cannulated trocar is used. The instrument assembly is pushed with a counterclockwise turning motion over the first guide wire. The working sleeve must not be inserted into the bone without the side-opening cannula. This could damage the working sleeve and obstruct stent insertion. It is mandatory not to hammer on the side-opening cannula, cannulated trocar and working sleeve.

The working sleeve can also be placed without the mounted cannulated trocar (working sleeve with side-opening cannula over guide wire). Then, there is more clearance between the diameter of the guide wire and the side-opening cannula in order to allow for minor correction in the trajectory when positioning the working sleeve. This can lead to a slight resistance when penetrating the bony vertebral body surface. Working sleeve placement must be monitored under lateral X-ray control [33]. The tip of the working sleeve must be advanced until it has penetrated the cortex and it is tightly seated into the bone.

When the working sleeve is inserted, the position of the guide wire must be carefully monitored, in order to confirm that it is not advancing forward [34]. It is possible to pull back the side-opening cannula in order to verify the positioning of the working sleeve. The same procedure must be repeated on the contralateral side. Once both working sleeves are in place, the side-opening cannulae with the inserted cannulated trocar and the guide wires must be removed. The working sleeves remain in the vertebral body. It is important to advance the instrument assembly carefully in order to avoid any injury to the physician's hand. The guide wire is longer than the combined length of the instrument assembly of working sleeve and the side-opening cannula and cannulated trocar will protrude through the handle of the side-opening cannula.

When using trocars for instrument positioning, creating the pathway and positioning of the instrumentation is achieved in one step. Either a transpedicular or extra-/parapedicular access may be selected depending on the anatomy of the vertebral body to be treated. With either access technique it is important to plan to place the two stents symmetrically towards the midline [35].

CREATE ACCESS CHANNEL

Drill [Figure 11] followed by blunt plunger [Figure 12] are used through the working sleeves to create an access channel for the stents. It is important to use lateral X-ray intensification in order to avoid the penetration into the anterior cortex of the vertebral body [36]. It is essential to avoid overdriving these instruments into vascular structures beyond the anterior cortical wall. For the same reasons, it is mandatory not to use a hammer to drive the drill forward [37]. The drill may aggressively advance with rotation. The plunger can be driven forward with light hammer blows. It is mandatory to ensure that the hammer blows hit the protruding metal pin and not the plastic handle. While using drill or plunger, it is important to ensure that the working sleeves are not moving [38]. The drill or plunger must not be used for manipulating or correcting the direction of the working sleeve. The same procedure must be repeated on the contralateral side.

In general, these are the same steps for each type of third generation device for percutaneous vertebral augmentation procedure. From this point, the difference is the type and the shape of the device. But, anyway the last step that is common for each device is the PMMA injection.

Figure 11.

Figure 12.

There are different type of cement formulas. They have an different radiopacity and different working time and viscosity. Some of these cements are ready for immediate injection, others require several minutes before they can be used. It is mandatory to consider the temperature of the setting time because it could influence the cement properties, like the viscosity that is a fundamental for cement leakage controlling. If a cement has a low-viscosity, it should not be injected. In addition, small syringes or plunger technique seem to be the best system to inject cement because in this way it is possible to have a direct feedback during cement injection and to provides the best way of injecting high-viscosity cement [39].

The fundamental steps of a correct cement injection are [40, 41, 42]:

- The cement must be prepared but it can be injected only when it has reached the correct viscosity
- Cement injection must be controlled under lateral x-ray vision and with intermittent AP checks.
- The injection must stopped if any cement leakage is observed. On the basis of the cement type, the injection can be resumed after 35 o to 160 seconds.
- The filling procedure can be completed until the vertebral body is supported from the upper to the lower endplate respectively
- After the cement injection, the cannula can be removed when the cement has set.
- The maximum amount of cement that can be injected safely in one session is about 25 cc

Chapter 28

ALTERNATIVES TO PMMA FOR VERTEBRAL AUGMENTATION PROCEDURES

Daniele Vanni^{1,*} and Vincenzo Salini²

²Orthopaedic and Traumatology Department, “G. d’Annunzio” University, Chieti, Italy

The acrylic bone cement plays an important in spine surgery. The polymethylmethacrylate (PMMA) has been extended from the field of ophthalmology and dentistry to the orthopaedics, as acrylic cement is used for prosthetic implants fixation, for osteoporotic, tumoral or metastatic remodeling areas and for vertebral fractures treatment [1, 2].

The PMMA bone cement was also found to be a good carrier for the antibiotic release at the infection site. PMMA is the gold standard for treatment of painful vertebral fractures by percutaneous vertebral augmentation procedures, but significant drawbacks are associated with its use, i.e., pulmonary embolism, toxicity of the methylmethacrylate monomer, heat generated during curing, and increased stress on adjacent vertebra [3]. In recent years the scientific advancement and research in the field of biomaterials have been an essential boost to search for alternatives to the PMMA. Over the past 20 years, the experimental study of acrylic biomaterials like bone cement, bioglass, cement additives, cement absorbable antibiotic, has become particularly significant, suggesting the evaluation of numerous models and projects [4]:

- the study of composite materials, formed by low polymerization temperature bone cement and bioglass fibers, with the aim to create a bioactive surface in contact with the bone
- a bone cement with sodium fluoride in order to provide a controlled release pharmacological system, able to prevent bone resorption.

* Corresponding Author’s Email: danielevannimd@libero.it.

- measurement of superoxide anion in cultured human leukocytes, as an indicative parameter of the materials reactivity.
- evaluate the tolerance and activity of the fluoride added cement, in cultured adult human osteoblastic cells, with particular attention to the actual availability of fluoride in the time of contact with the surface containing the additive compound, evaluating the biocompatibility and the osteoconductive capacity of a new acrylic bone cement.

PMMA is commonly used as a filler material, but unfortunately a range of issues to be resolved are associated with its use.

In fact, the PMMA has a modulus of elasticity and stiffness different from that of the vertebral column and its use could change the normal biomechanics of the spine, resulting in subsequent fractures of the vertebrae, above or below [5, 6, 7, 8, 9].

The “adjacent level insufficiency fractures”, following percutaneous vertebral augmentation procedures seem to be due to the abnormal stresses that are generated when a “super vertebrae” is created. Especially in case of osteoporotic vertebral fractures, the “non-augmented vertebrae” have lower structural integrity, that is due to disease. Reports of up to 52% of osteoporotic spines treated with either vertebroplasty or kyphoplasty sustained adjacent level fractures within a 7-year period [10]. Deramond and Mathis [11] report a significant increase of “adjacent vertebrae fractures”, probably resulting from a shift in the normal load transmission through the spine following percutaneous vertebral augmentation procedures. Lieberman et al. [12] shows an abnormal load and motion distribution in vertebral segments treated with percutaneous vertebral augmentation procedures. In addition Farooq et al. [13] reports that percutaneous vertebral augmentation procedures reduce annulus and neural arch stress concentrations: as a result there is a greater compressive stress concentration on the intervertebral disc and on the adjacent vertebral bodies. In addition, the PMMA reaches a high polymerization temperature and this can represent a problem when it is used near very delicate structures, such as meninges and spinal cord. Though the PMMA is able to provide an immediate and good primary stability, since it acts as an inert material, it cannot be reabsorbed over the time nor it has the ability to biointegrate with bone tissue around. This has therefore led to the search for alternatives to PMMA. The goal is to find materials capable of providing an immediate absolute stability during vertebral augmentation procedures, without presenting the problems of the high polymerization temperatures. It should also be capable of bone bio-integration, over the time.

For these reasons, it is fundamental to evaluate the biomechanical properties of different vertebral augmentation agents in a reproducible vertebral body model, able to mimic the physiological conditions in a reproducible way. In addition, it is mandatory to describe the biomechanical effects of these agents on the surrounding spinal column through comparative analysis.

Until now, four different filler materials seem to be usable: (1) SRS-tricalcium phosphate cement; (2) MIIIG X3 HiVisc, calcium sulfate cement; and (3) BoneSource, calcium phosphate cement. In the study of Clint Hill et al. [14] the same amount of liquid (5 mL) was used in each augmentation and each vertebra was augmented bilaterally via injection of two 2.5 mL volumes of the investigated material [15]. The vertebrae were then tested in the lab through mechanical testing load frame. Each vertebra was compressed under a stroke-controlled loading regime in order to evaluate the construct’s elastic modulus in compression. Mechanical testing was stopped in case of a compressive displacement of 6 mm or

mechanical failure (denoted by a rapid decrease in the measured compressive load, greater than 15% of the current load) [16, 17, 18]. From the study of Clint Hill et al. the mean modulus of elasticity for the control group vertebrae was 92.44 ± 19.28 MPa; SRS-tricalcium phosphate group was 79.14 ± 20.20 MPa ; BoneSource group was 57.49 ± 8.35 MPa. The mean modulus of elasticity was highest in the PMMA group (195.47 ± 2.33 MPa) and lowest in the MIIG group (25.79 ± 4.77 MPa). On the basis of these data it is possible to establish that PMMA is stiffer than the other materials. Calcium phosphate and calcium sulfate revealed a similar modulus of elasticity to the nonaugmented vertebrae and they are not stiff as PMMA but they are able to sustain significant loads. These data suggest that the characteristic of the filler materials may influence the “adjacent segment fracture phenomenon” resulting from percutaneous vertebral augmentation procedures [19, 20, 21, 21, 23, 24]. However, although alternative osteoconductive filler materials might prevent subsequent vertebral compression and fractures because they are less stiff than PMMA, without causing exothermic effects, [25, 26, 27], they may not provide enough initial stiffness. Therefore, according to D. H. Heo et al. [28] recollapse may occur 1 year after in the CaP-augmented vertebrae [29]. A newly available alternative to PMMA is a containment system that enables percutaneous bone graft augmentation of the fractured vertebra.

Minimally invasive percutaneous vertebral augmentation with intravertebral polyethylene mesh sac is a new system used in the minimally invasive biologic vertebral reconstruction procedures [30]. It consists of a polyethylene mesh sac, introduced into the vertebral body and filled with morcelized bone allograft. Bone graft is able to create a hyperdense pack, reducing the fracture and restoring vertebral height. Osteoconductive and osteoinductive properties allow a biologic vertebral reconstruction. The adjacent vertebrae should be more protected by a construct with a similar elasticity and physical characteristics of the morcelized bone. In fact the use of bone tissue (autologous / homologous) is still considered the "gold standard" in spinal instrumentation surgical techniques in order to facilitate spinal arthrodesis formation. Autologous bone has the greatest osteogenic potential, but its availability is limited and its use may be associated with painful long-term complications. The use of homologous bone is an important option in case of bulk or structural graft. Bone graft augmentation offers fracture reduction and trabecular stabilization. Long-term findings suggest that bone graft augmentation in osteoporotic patients yields a stable yet less rigid segment, which may reduce the risk of adjacent level fracture. For younger people, the potential now exists for biologic fracture repair. The limitations of the autologous bone substitutes, make it necessary to search for alternatives. Till date, the synthetic bone substitutes represent a partial solution, because they provide some bone mechanical properties such as osteoinductivity and osteoconductivity, but this features remain largely dependent on the presence of vital periosteum and bone [31]. The advent of bone substitutes and composites of biological factors represents a promising development in the search for synthetic bone grafts that are able to substitute the mechanical and osteogenic properties of the bone tissue.

SE SERVE PUOI AGGIUNGERE.....

A promising alternative is resorbable, nano-crystalline calcium phosphate cement (CPC), which is biocompatible, biomimetic and having extensive clinical history. Additionally, these

CPCs can be used as delivery vehicles for bioactive molecules to accelerate healing and treat osteoporosis which is typically the root cause of the vertebral fractures.

However, use of pure CPC in vertebral augmentation has been limited due to reports of cardiovascular deterioration. This effect has been associated with cement extravasation leading to pulmonary embolism stimulating thrombosis. In order to minimize these risks, a new class of combination CPCs have been developed with enhanced viscosity, cohesiveness and improved radiographic visualization. Unlike other CPCs discussed in the literature, these combination CPCs do not initiate a thrombotic response.

RESULTS

Results of human cadaver vertebral injections testing are summarized in Table 1. Overall, nano-crystalline CPC combination biomaterials were easy to inject and visualize under fluoroscopy. Individual formulations were resistant to leakage and exhibited symmetrical, well defined flow characteristics. Conversely, the PMMA controls exhibited finger-like protrusions indicative of poor resistance to leakage (Figure 1). From an initial 13 formulations, 8 (62%) could be injected easily, 100% were resistant to leakage and exhibited symmetrical and well defined flow characteristics. It was observed that cement injection force, leakage and dispersion were related to CPC formulation design (molecular weight of the viscosity modifier, weight percent of the modifier, ratio of liquid to powder) but not by the nature and concentration of contrast agents.

DISCUSSION

This new class of modified CPCs were easy to inject and visualize. Many formulations exhibited improved resistance to leakage and dispersion relative to PMMA. Injection force, leakage and dispersion were related to CPC formulation and can be tailored for optimal performance. Additionally, these CPCs did not exhibit a tendency to initiate thrombosis. These combination formulations may significantly reduce the risks historically associated with CPC and are an attractive alternative to PMMA due to their biocompatibility, mechanical properties and resorbability.

STEM CELLS AND BIOTECHNOLOGIES FOR VERTEBRAL AUGMENTATION PROCEDURES

Andrea Pantalone*, MD, Matteo Guelfi, MD and Vincenzo Salini

Orthopaedic and Traumatology Department, “G. d’Annunzio” University, Chieti, Italy

INTRODUCTION

Regenerative medicine is recently developed into a multidisciplinary branch aimed to replace or restore normal function of cells, tissues, and organs that are damaged by disease. Unlike conventional surgical therapies, which, although including some element of reconstruction, they remain predominantly ablative for most diseases.

Regenerative medicine incorporates the fields of tissue engineering, cell biology, nuclear transfer and materials science to allow a truly regenerative approach by reconstructing, repairing, or replacing missing or damaged tissue to a state as close as possible to its native architecture and function [1, 2].

In the last two decades, regenerative medicine has shown the potential for “bench-to-bedside” translational research in specific clinical settings. A crucial point in regenerative medicine is represented by the cell type to be transplanted (stem cells) in the affected patients, alone or in conjunction with specific biomaterials (scaffold) [3, 4]. Stem cells have been proposed as a powerful tool in the treatment of several human diseases, both for their ability to represent a source of new cells to replace those lost due to tissue injuries or degenerative diseases, and for the ability of produce trophic molecules able to minimize damage and promote recovery in the injured tissue [5, 6].

Different cell types (embryonic, fetal or adult stem cells), human fetal tissues and genetically engineered cell lines have been tested for their ability to replace damaged cells and to restore the tissue function after transplantation [7].

Based on their origin, whether from the individual to be treated or from a donor, these cells can be defined as autologous or allogenic. Autologous cells would represent the ideal

* Corresponding Author’s Email: pantaloneandrea@libero.it.

transplantation source, since they are not rejected by the immune system, avoiding the use of immunosuppressant drugs.

Nevertheless, the use of these cells is limited by their low “ex vivo” expansion abilities, particularly in cases of patients with end-stage organ disease who do not produce enough cells for transplantation [8].

In these cases, the use of allogenic cells may represent an advantage, but this may require the creation of specific cell banks, able to provide a large number of samples from different donors immunologically matched with the potential patients [9].

Spinal surgery is a field that is rapidly changing and evolving; the use of biologics (stem cells) has now become widespread. Actually autologous (bone marrow aspirate and mesenchymal stem cells, adipose stem cells) or allogenic stem cells are not yet in routine clinical use in spine surgery but these approaches have also been studied for achieving spinal fusion in order to treat degenerative and traumatic spine diseases [10].

Barbanti Brodano G. et al. (2012) demonstrated that human mesenchymal stem cells obtained from the bone marrow in combination with bioceramics (bone substitutes composed of calcium and phosphate complex salt derivatives) seem to be an alternative to the autologous or allogenic bone fusion in spine surgery [11].

This *in vitro* study shows how stem cells, together with a scaffold, should enable in reaching successful spinal fusion according to the correct principles of regenerative medicine and bypassing the drawbacks of traditional treatment (autologous bone grafts and allografts), including limited availability, donor site morbidity, risk of disease transmission and reduced osteogenicity [12, 13].

In order to be used for regenerative medicine on a large scale in spinal surgery, ‘the perfect cells’ (autologous or allogenic) to be transplanted must show the following features [14]:

- *Accessibility*: the collection of cells should not require the use of invasive procedures;
- *Availability*: the cells should be readily available in large number for transplantation;
- *Plasticity*: the cells should be able to differentiate in different cell types;
- *Mitotic stability*: the cells should retain a stable karyotype along several cell divisions;
- *Low risk*: the use of the cells should not induce transplanted related diseases, such as immunoreaction and cancer;
- *Ethical acceptability*: the use of the cells should avoid ethical concerns.

In future stem cells could become the gold standard strategy for achieving spinal fusion [15].

Chapter 30

BROW LIFT

Richard Baker^{1,*} and Afshin Mosahebi^{2,†}

¹Broomfield Hospital, Chelmsford, UK

²Royal Free Hospital, London UK

KEY POINTS

- Aesthetic results are equivalent between open brow lift (OBL) and endoscopic brow lift (EBL) (level III evidence).
- Complication rates are low for both procedures (level III evidence).
- Patient satisfaction is high for both procedures (level IV evidence).
- Scalp sensation is impaired to a greater degree in OBL in the short term but in the long-term this difference diminishes (level III evidence).
- Temporary change in scalp sensation is a significant symptom for patients in both groups (level IV evidence)

INTRODUCTION

The forehead occupies a prominent position in the upper third of the face and is often the first site for the appearance of rhytids. Many people choose to improve forehead rhytids with the use of botulinum toxin, the soaring demand for which reflects the aesthetic importance of the forehead. However, brow lift procedures reduce rhytids more and improve brow position with much greater longevity. In 2011, 47,000 brow lifts were performed in the United States (up from 42,000 the previous year [1]) and 1500 were performed in the UK [2]. Female patients currently outnumber males by ten to one, but as the demand for male cosmetic surgery increases the difference is likely to reduce. The concept of forehead rejuvenation dates back over 100 years in the literature [3]. Hunt described elevation of the eyebrows using direct, coronal and anterior hairline (pretrichial) skin excisions in 1926 [4].

† Corresponding Author's Email: info@londonplasticsurgerycentre.com.

Gonzalez-Ulloa in 1962 and Loeb in 1970 described the modern coronal brow lift combined with a facelift using a continuous incision [5, 6]. Marino and Godolpho (1964) and more recently Adamson et al. (1985) introduced the concept of brow muscle modification to reduce forehead rhytids [7, 8]. New approaches to the open brow lift (OBL) such as transblepharoplasty and lateral approaches have since been presented, all possible planes of dissection – subcutaneous, subgaleal, subperiosteal, biplanar – have been described and many methods of fixation attempted [9]. The endoscopic brow lift (EBL) was introduced by Isse in 1994 and has since been popularised by Ramirez [10]. Both open and endoscopic procedures, and their variants, are currently widely practised and no consensus has emerged regarding the superiority of any one.

LITERATURE OVERVIEW

Publications looking at brow lift procedure were identified using a PubMed search and the search term ‘forehead [MeSH] OR brow [MeSH] AND ‘lift’ [MeSH] in October 2012. Hits were filtered for those specific to brow lift, and the relevant papers reviewed and assigned a level of evidence (LOE) adapted from the American Society of Plastic Surgeons (ASPS) Scales for Rating Levels of Evidence (Appendix) from which graded recommendations were derived.

The literature search yielded 492 hits, of which 485 were relevant to brow lifting. Ten non-English language papers were excluded. Dates of publication ranged from 1972 to September 2012. There was one study of Level II evidence, fourteen at Level III, 117 papers at Level IV and 163 papers at Level V evidence. The manuscripts comprised fifty reviews, ninety discussions and comments on points of technique, and sixty case series. Endoscopic brow lift (EBL) was exclusively addressed by 79 publications. Other popular topics were anatomy and aesthetics (21 papers) and fixation devices (44 papers).

ANATOMY AND AESTHETICS

The literature referring to anatomy and aesthetics of the brow is composed completely of anatomical live patient and cadaver studies and thus amounts to level V evidence.

Skin and underlying muscle contribute to forehead rhytids. Forehead muscles have a superficial, intermediate and deep layer, with an anatomically distinct depressor superciliary muscle and a brow fat pad that allows movement of the eyebrows [11].

The wide mobility of the scalp and forehead is due to an anatomical gap in the deep layer of the subcutaneous fascia [12]. This anatomy accounts for the brow lifting effect of division of the corrugator supercilii and procerus muscles.

Aesthetically pleasing brows (Figure 1) are usually described as having a lateral peak located at the junction of its medial two-thirds and lateral third, or alternatively the lateral limbus of the iris [13].

However, an observational study comparing eyebrow peaks with anatomical landmarks in fifty subjects found that the deep temporal fusion line is the most reliable landmark in both males and females [14].

Data from McCord CD Jr, Codner MA. *Eyelid and Periorbital Surgery*. St Louis: Quality Medical Publications; 2008.

Figure 1. The aesthetic brow. The medial extent of the brow (B) is vertically aligned with the lateral aspect of the ala (A). The lateral extent of the brow (C) is horizontally aligned with the medial extent (B) and along a line formed by the ala and lateral canthus of eye. The lateral edges of the limbus (D) is vertically aligned with the brow's highest point (E).

An anatomical study in twelve cadavers suggests the characteristic shape of the brow has a ligamentous basis [15]. There are three retaining ligaments medially and one laterally, beginning approximately one centimetre from the midline and one centimetre above the supraorbital rim. The medial three ligaments extend from the cranium into the forehead musculature, whereas the lateral ligament extends in a sheet-like fashion across the lateral aspect of the supraorbital rim.

Ageing is accompanied by relatively greater descent of the lateral brow. A study measuring the brows of seventy volunteers determined that, counterintuitively, it is higher in fifty to sixty year-olds than twenty to thirty year-olds at all points along its length but significantly so at the medial and mid-brow points [16]. Knize postulates in a study of forty cadaver half heads that relative lateral brow descent is due to a greater effect of descending forces on the lateral eyebrow (gravity, corrugator supercilii and lateral orbicularis oculi) compared with elevating forces (frontalis muscle resting tone) [17]. This helps to account for the observation that selective elevation of the lateral brow has a rejuvenating effect whilst over-elevation of the medial brow imparts an unaesthetic surprised appearance.

The supraorbital, supratrochlear and frontal branch of the facial nerve must be avoided during brow lift surgery. In a study of 75 cadavers, Cuzalina et al. located the supraorbital nerve within an average 0.56mm +/- 0.7mm of a line extending from the medial iris vertically upwards (rather than along the oft-quoted mid-pupillary line) and the supratrochlear nerve an average of 9mm medial to it [18]. In an examination of fifty skulls by Miller et al. the supratrochlear nerve was never closer than 1.6cm to the midline at the level of the supraorbital ridge, and there were no supratrochlear foramina [19]. Theoretically sensory nerve injury is less likely if corrugator supercilii, procerus and orbicularis oculi muscles are disinserted rather than resected. Hafezi et al. found rates of permanent sensory loss following EBL with conventional muscle resection versus EBL with muscle disinsertion of 13.6% and

4.5% respectively [20]. However, muscle resections were performed early in the series and the disinsertions later, so there is the possibility of a learning curve effect.

Based on a study of 26 cadavers by Liebman et al., the frontal branch of the facial nerve runs *within* the superficial musculoaponeurotic system (SMAS), which in the brow becomes the temporoparietal fascia [21]. Caution must be taken in interpreting the findings from the cadaver studies described as the anatomy can vary modestly from the *in vivo* setting.

OPEN BROW LIFT TECHNIQUES

Modern open brow lift techniques vary in two principal ways: the pattern of skin incisions/excisions; and the plane in which the forehead flap is elevated.

Incision Type

Multiple incisions are described for OBLs, aiming either to reduce specific complications or enhance certain effects (Figure 2). In 1962 Gonzalez-Ulloa described a straight coronal incision, followed in 1972 by Regnault's combined coronal and facelift incisions [5, 22]. Gleason in 1973 described two temporal incisions specifically to elevate the lateral brows [23]. Ortiz-Monasterio in 1978 described the classic wavy coronal incision brow lift [24]. The main incisions in use today are: direct; (bi)coronal; pretrichial/trichophytic and lateral (the terms 'bicoronal' and 'coronal' are used interchangeably in the literature in the context of brow lifting).

Modified from Guillot JM, Roussou DE, Replogle W. Forehead and scalp sensation after brow-lift: a comparison between open and endoscopic techniques. *Arch Facial Plast Surg*. 2011;13(2):109-16.

Figure 2. Incisions for brow lifts: 1. Direct; 2. Mid-forehead; 3. Temporal/cheek; 4. Endoscopic; 5. Trichophytic; and 6. Coronal.

Direct Brow Lift

The direct brow lift, in which a melon slice of skin is excised directly above the eyebrows within a relaxed skin tension line, is technically straightforward and predictably elevates the eyebrows although with poorly concealed scars [25]. It is better suited to men owing to their thicker skin, straighter brows, higher and/or thinner hairlines and lower aesthetic demand. In a retrospective questionnaire study of 28 patients (43 brows) of both genders, a 'happy' or 'very happy' response was given by 81% for cosmesis and by 74% for the degree of lift attained [26]. However, paraesthesia or numbness was noted postoperatively in 51% of brows. All procedures were performed for facial nerve palsies or involutional changes and it is for these patients rather than cosmetic patients that direct brow lifts are recommended [26].

Bicoronal and Pretrichial Brow Lift

The bicoronal incision placed within the hairline is the conventional OBL incision. Since this results in excision of hair-bearing scalp, in patients with receding hairlines it can be brought forward to the anterior hairline border to enable excision of non-hair-bearing skin. The latter excision is termed 'pretrichial' or 'trichophytic', although 'trichophytic' can also refer to a particular type of camouflaging closure technique (described later).

After measuring the foreheads of fifty volunteers, McKinney et al. concluded that a bicoronal incision is better for brows shorter than 5cm in height whilst a pretrichial incision is ideal for taller brows [27].

Cilento and Johnson found low complication rates in their retrospective review of 1,004 OBLs using both coronal and trichophytic incisions, and a questionnaire returned by 416 patients (64%) demonstrated a 99% satisfaction rate [28]. Unfortunately there was no comparison of the outcomes for coronal and pretrichial incisions [28].

A series of 600 OBLs utilising a coronal incision in the subgaleal plane revealed a 4% overall complication rate after five years follow-up, the most common of which was persistent scalp paraesthesia [29]. Table 1 compares complication rates from series of coronal and pretrichial OBLs. Whilst differences between publications in defining or detecting complications preclude statistical comparison of this data, on the whole complication rates appear to be low for either procedure. Table 2 compares satisfaction rates for the three main OBL incisions. Few papers report patient satisfaction rates and those that do either do not state how it is measured or use methods that have no reference to previous literature. Frequently papers state that 'patient satisfaction was very high' with no numerical evidence. However, what little evidence there is suggests that patient satisfaction is high with all three procedures. Revision rates are very rarely mentioned. Those reported are 0.57% (bicoronal and pretrichial), 0.83% (bicoronal) and 0% (pretrichial) [28, 29, 30].

The primary disadvantages of the coronal and pretrichial approaches are the long incisions and consequent scars, and the risk to sensory nerves. A strategy used to reduce scar visibility is to conceal it with hair regrowth. Traditionally incisions were bevelled parallel with the hair follicles preserving the maximum numbers of hair shafts to subsequently cover the scar. An alternative approach is the trichophytic incision in which the bevel is perpendicular to the hair shafts. This transects the hair follicles just deep to the epidermis such that subsequent hair growth is through the scar [34]. Camirand and Doucet compared the two types of incision in a prospective randomised controlled trial (RCT) in thirty patients

[35]. In each patient one half of the incision was parallel to the hair shafts and in the other half the incision was perpendicular to the hair shafts (trichophytic).

Table 1. Comparison of complication rates between bicoronal and pretrichial OBLs from published case series

Complication	Coronal (%)	Pretrichial (%)
Hematoma	0 [28] <1 [29]	0 [28] 2 [30] 3.7 [32]
Permanent numbness or dysaesthesia	1.2 [28] <3 [29]	0 [31, 32] 1.2 [28] 10 [30]
Permanent alopecia	0.7 [28] <1 [29]	0 [31, 32] 0.7 [28] 12 [30]
Permanent frontal branch weakness	0 [28, 29]	0 [28, 30, 31]
Ocular irritation	0 [29] 7.4 [28]	0 [30, 31] 7.4 [28]
Poor scarring	<1 [29]	10 [30] 1.6 [31] 0 [32]
Overall complication rate	4 [29]	2.2 [31], 3.7 [30]

Table 2. Comparison of satisfaction rates between bicoronal, pretrichial and lateral OBLs

	n	Follow-up (yrs)	Bicoronal (%)	Pretrichial (%)	Lateral (%)
Cilento and Johnson 2009 [28]	416	5	99.5	99.5	
Freidland et al. 1996 [29]	600	5	98		
Vogel and Hoopes 1992 [30]	50	7.5		90	
Fogli 2003 [33]	270	5.5			88

In 95% of patients the trichophytic scar was significantly better in terms of visibility, nonlinearity, absence of hypopigmentation and the abundance of hair into and in front of the scar [35].

Lateral Brow Lift

The lateral brow lift avoids a coronal incision altogether by confining incisions to the temporal regions. Proponents argue that the technique is simple, yields an efficient lift without elevating the medial brow, may improve the hairline and reduces wrinkling of the medial forehead [36]. Knize's variation of the lateral brow lift uses two temporal scalp incisions to elevate and suspend the lateral eyebrows and two upper blepharoplasty incisions to access the procerus and corrugator muscles [37]. In a 140 patient case series 'most' patients experienced scalp dysaesthesia that typically recovered by six to twelve weeks [37].

Complication rates presented in lateral brow lift series are summarised in Table 3. Notable is the three to five percent incidence of temporary frontal branch palsy, considerably higher than that reported for other types of brow lift.

Dysaesthesia remains troublesome as in other OBLs although the assessment of this symptom clearly varies significantly, with Fogli reporting no occurrences whilst Knize says most of his patients develop temporary dysaesthesia [33, 37].

Table 3. Complication rates in published series of lateral brow lifts

	n	Mean follow-up (yrs)	Dysaesthesia (%)	Frontal branch palsy (%)	Alopecia (%)	Longevity (yrs)
Knize 1996 [37]	140	0.25 - 4	'Most'*	5*	>2	-
Fogli et al. 2003 [33]	270	5.5	0	3*	1.5	-
Badin et al. 2010 [38]	44	3	18.2	4.5*	0	3

not stated; *temporary.

Fogli's case series measures outcome by surgeon assessment (using a three point scale) of three criteria: distance between eyelashes and brow; improvement of crow's feet; and improvement of lower eyelid and malar wrinkling [33]. 81% of patients were judged to have very good or good aesthetic results [33]. Badin et al. measure the brow lifts at 1.5 and three years by calculating ratios of mid-pupil to lateral canthal distance to the vertical distance to the eyebrow [38]. However, insufficient data is provided to convert this into a simple brow elevation distance in millimetres that can be compared with other series. Whilst it does demonstrate a statistically significant elevation at postoperative follow-up, its aesthetic significance is hard to judge [38].

Planes of Dissection

The forehead flap has been elevated in various planes, aiming to improve the magnitude and longevity of lift whilst reducing rates of flap necrosis, hypertrophic scarring, scalp dysaesthesia and alopecia. The subcutaneous and subgaleal planes are the most commonly used in OBLs (EBL uses the subperiosteal plane) although most techniques incorporate a subperiosteal plane just above the supraorbital rim to avoid the supraorbital and supratrochlear nerves and give greater mobility to the brow. Superficial transverse rhytids can be more easily addressed in the subcutaneous plane because it allows greater stretch of the skin whilst also posing less risk of transecting sensory nerves. However, the subcutaneously elevated flap has a poorer blood supply than the thicker subgaleal flap, which may affect viability. Despite this, Wolfe and Baird found no wound healing problems in 27 female patients who had subcutaneous OBL, no alopecia and only temporary loss of scalp sensation posterior to the incision [32]. The technique produced long-term (mean follow-up of 7.5 years) patient-assessed wrinkle reduction in a retrospective review of fifty patients [30].

Pollock and Pollock used progressive tension sutures between the skin flap and galea in a series of eighty patients to sustain brow elevation [39]. Although there were no relapses, average follow-up was only 13.5 months [39]. Niamtu reported high patient satisfaction in a case series of fifty patients who underwent subcutaneous brow lift, although without explaining how this was assessed [4].

Dissecting the frontal flap in a subperiosteal plane with release of the orbital rim periosteum has the advantage of reducing the risk to the sensory nerves and frontal branches of the facial nerve [43]. In his series of 92 patients undergoing bicoronal subperiosteal OBL with up to seven year follow-up, Ramirez presented two cases of alopecia, no 'significant' cases of scalp dysaesthesia, no recurrent brow ptosis, maintenance of brow position and 'extremely high' patient satisfaction [42].

Table 4. Complication rates for case series of OBLs using different planes of dissection

Series	Type	n	Follow-up (yrs)	Delayed healing (%)	Poor scarring (%)	Partial flap necrosis (%)	Alopecia (%)	Scalp dysaesthesia (%)	Relapse rate (%)	Revision rate (%)
Wolfe and Baird 1989 [32]	PT, BC, SC	27	X	0	0	3.7	0	100 (T)	0	0
Vogel and Hoopes 1992 [30]	PT, SC	50	7.5	0	<10	0	12 (T); 12 (P)	10	0	0
Pollock and Pollock 2007 [39]	PT, SC	80	1.1	1.3	0	1.3	1.3	0	0	1.3
Niamtu et al. 2008 [40]	PT, SC	50	2.5	0	0	4	0	0	0	0
Friedland et al. 1996 [29]	BC, SG	600	5	0	<1	0	<1	<3	0	<1
Troilius 1999 [41]	BC, SG	60			6.7		10 (T)	X		
Fogli 2003 [33]	L, SG	270	5.5	0	0	0	1.5 (T)	0	0	0
Knize 1996 [37]	L, SP	140	0.25 - 4	0	0	0	>2	'Most'(T)	3.5	5.7
Guyuron and Rowe 2008 [31]	PT, SG	297	1-8	2.2	0	0	0	0	-	-
Ramirez 1995 [42]	BC, SP	92	Up to 7	0	0	0	2	0	-	-

PT = pretrichial; SG = subgaleal; L = lateral; BC = bicoronal; SC = subcutaneous; SP = subperiosteal; T = transient; P = permanent; X = not recorded.

Complication rates for OBL using different dissection planes from various case series are summarised in Table 4. Rates are mostly below five percent but range from from zero to twelve percent for permanent alopecia and 0-100% for transient dysaesthesia. This probably represents differences in the definition of these complications rather than true differences. Definitions are typically not provided so this cannot be verified.

Several authors have combined dissection planes (biplanar lifts) aiming to achieve the benefits of each, such as greater flap mobility, less risk of sensory disturbance and longer lasting results. Ramirez used his biplanar brow lift in 24 patients with high foreheads with a mean follow-up of ten months [44]. It begins with a pretrichial incision and subcutaneous dissection followed by subperiosteal dissection with endoscopic control from the mid-forehead onwards. Ramirez reported one incidence of superficial forehead flap necrosis and two hematomas. Numbness was found in the area of subcutaneous dissection in all patients for up to twelve months but sensation posterior to the incision was preserved [44]. Although the aesthetic results are described as 'very satisfactory', no objective measures are given.

Aldo Mottura uses a bicoronal incision with dissection in the subcutaneous and subgaleal planes. In a series of fifty patients with up to four years follow-up, episodes of postoperative paraesthesia resolved spontaneously, there were no wound healing problems and brow elevation was as effective as with frontal lifts with galea transection (an historical control group) [45].

A similar technique involving temporoparietalis fascial, galeal, and periosteal imbrication without division of the galea achieved an average of 5mm of lateral brow elevation with partial relapse in five cases and transient alopecia in six cases (six to eight months) in a case series of 32 patients [46]. Karabulut and Tümerdem combined subperiosteal and subgaleal dissection planes, describing a coronal incision, subgaleal elevation until 2.5cm from the supraorbital rim and subperiosteal dissection thereafter [47]. No patient showed significant brow descent over an average of 34 months follow-up [47].

There is evidence that the greater mobility of biplanar flaps enables more skin resection. Marshak et al. used biplanar dissection of the skin and SMAS in the temporal region in their lateral brow lift in 37 patients, excising more skin using the biplanar technique compared with the control uniplanar subSMAS group (mean 21.8mm versus 15.1mm respectively) [48].

Open Brow Lift Combined with Other Procedures

For the purposes of research it is optimal to perform OBL in isolation to avoid the complexities of estimating competing effects of different procedures. However, in practice many patients request and surgeons perform simultaneous procedures, summarised in Table 5. The commonest combination is with upper blepharoplasty. As this procedure may exacerbate a compensated brow ptosis, it is advisable to perform the brow lift first [49, 50]. In their 600 patient case series, Friedland et al. reported combined upper blepharoplasty and brow lift with aesthetic results reported as excellent in 100% of patients, although no supportive data was included [29].

Similarly, Fogli performed simultaneous lower blepharoplasties in 241 patients with subjectively satisfactory results [33]. Dempsey et al. combined OBL with midface lifts in 130 patients to (subjectively) produce a natural and long-lasting result [51].

Other techniques that can be combined with OBL to improve aesthetic results include release of upper midface ligamentous structures, wide undermining of orbicularis oculi and suspension sutures to improve the lateral brow and elevate cheek fat [52].

ENDOSCOPIC BROW LIFT

There are 79 papers that discuss EBL from 1994 onwards. EBL was first described in the literature by Isse following presentation of the work in 1992 [10]. This was a 58 patient case series in which some of the EBL procedures were combined with endoscopic face lifts. The overall complication rate was 18% including seromas, ecchymosis and prolonged numbness (two patients) [10]. This procedure used a subperiosteal dissection plane with release of the periosteum from the orbital rim. The need to resect certain muscles – corrugators, procerus, orbicularis and even the frontal muscle – was soon recognized [54]. Excess skin is accommodated by dissecting the scalp posteriorly and various methods of securing the scalp flap to the skull have been described and are detailed later [55].

Proponents of EBL over OBL feel that it has less risk of alopecia, reduced tissue trauma, small camouflaged scars, less bleeding and oedema, improved postoperative comfort and faster recovery.

Table 5. Proportion of OBLs in published case series combined with other procedures

Case series	n	Upper bleph (%)	Lower Bleph (%)	Facelift (%)
Ramirez 1995 [42]	92			100
Friedland et al. 1996 [29]	600	100	0	86
Troilius 1999 [41]	60	50		
Fogli 2003 [33]	270	93	89	63
De Cordier et al. 2002 [53]	400	50	50	86

For these reasons Ramirez predicted as early as 1997 that EBL would become the first line choice for forehead rejuvenation [56]. The main disadvantage of the endoscopic approach is that excess skin cannot be resected thus potentially raising the hairline [57].

A survey of 21 New York plastic surgeons in 2001 with an 84% response rate (21 of 25 surgeons contacted) found that seventy percent of patients but only fifty percent of surgeons were satisfied with the long-term results [58]. Complications included alopecia, hairline changes, infected hardware, brow asymmetry requiring revision, prolonged brow or forehead dysaesthesia, and frontal branch nerve paralysis. Interestingly, the number of EBLs being performed by these surgeons was declining significantly [58]. The authors postulate that this may be due to refinement of indications, the growth of alternative means of rejuvenation such as botulinum toxin and concerns about the procedure's efficacy [58].

Several studies (Table 6) demonstrate the efficacy of EBL in terms of brow elevation. This data is infrequently included in case series and comparison between series is difficult as measurement is non-standardised. Follow-up times vary and are often ambiguous. Furthermore, some papers document brow elevation at rest and during active elevation whilst other papers make no distinction. However, the papers all agree that EBL achieves an immediate postoperative brow lift of somewhere between four and twelve millimetres. The longevity of this effect is poorly recorded but there is consensus that the lift relaxes with time (from as early as four to six weeks in a minority of patients), lasts at least two years and declines in a linear fashion by approximately 1mm per year [59, 60, 61]. For example, Papadopoulos et al. found mean elevation of eight millimetres at two years dropping to 5.6mm at five years in 143 patients, with 63% saying they would be likely to repeat the procedure [61]. Reliable reduction in transverse and vertical rhytids is claimed in both a 67 patient and 400 patient case series, although without objective measurement [57, 53].

Complication rates from several EBL case series are summarised in Table 7. Alopecia and dysaesthesia are the commonest reported complications, ranging from 0-19% and 0-57% respectively. Poor scarring seems to be relatively uncommon - less than five percent in most series, although as high as 24% in that of Papadopoulos [61]. Transient mild sensory symptoms appear common but permanent sensory disturbance occurs in less than five percent of cases. Palsy of the frontal branch of the facial nerve is inconsistently mentioned but ranges from 0-2.5%. For example, in Marchac's series of 206 EBLs there were five cases of frontal branch palsy, all resolving by six months [63]. Permanent palsy appears to be rare and is not usually reported. However, across all complications the distinction between transient and permanent is often not made.

Complication rates also vary according to how the data is collected. In the series of Withey et al. data is derived from a patient survey and considerably higher complication rates are recorded than those based on surgeons' assessments quoted in other papers [64].

Table 6. Elevation of the brow achieved with EBL in several case series

	n	Follow-up (months)	Midpupil to brow (mm)	Mean brow elevation (mm)		Duration (yrs)
				Medial	Lateral	
De la Fuente and Santamaría 2002 [60]	207	12	8	2	10	-

T= temporary.

The distinction between side effect and complication, particularly in relation to scalp sensation and scarring, is rarely discussed and adds further imprecision to the documenting of complication rates.

Methods of Brow Fixation

The early brow lifts, such as Regnault's complete face and forehead lift with undermining and direct closure of the galea without cortical fixation, utilised subgaleal dissection [22]. However, as EBL came to the fore in the 1990s the plane of dissection changed to subperiosteal, thus mandating a method of cranial suspension. Since the first paper in 1994, considerable innovation has led to development of both permanent and bioabsorbable cranial fixation techniques (Table 8). Securing the elevated brow to the pericranium (rather than skull) has been achieved using sutures (absorbable and non-absorbable), electrocautery and glue [71, 72, 73, 62]. An absorbable subperiosteal suture achieved long-term (up to six years) brow elevation in a 300 patient case series [74]. Percutaneous fixation of supraorbital adhesions to the deep temporal fascia, specifically to address the lateral brow, maintained brow elevation at three years follow-up in 44 patients [38]. Imbrication of a temporoparietalis fascia/galeal/periosteal flap achieved an average of five millimetres lateral brow elevation in 32 patients [46].

The skull has the advantage of non-elasticity and is therefore commonly used in most EBL techniques. McKinney and Sweis described sculpted outer cortical tunnels and sutures for brow fixation with elevation maintained at five years [27]. Jones and Grover retrospectively compared fibrin glue periosteal fixation in 189 patients with PDS sutures tied through cortical tunnels in 349 patients and found significantly increased stability of brow elevation in the latter group [62]. Average brow elevation was 5.9mm at one month in the fibrin glue group, falling to 3.8mm beyond four months. In the cortical tunnels group the equivalent figures were each 6.2mm [62]. In both groups overall, there were two cases of significant although temporary alopecia and three cases of minor alopecia, four scar revisions and one reoperation for relapse [62]. Marchac et al. reported 86% good or excellent results (subjective assessments by surgeons) in their 206 patient case series using fibrin glue with a 7.8% complication rate [63].

Several permanent fixation methods have been described including posts and K-wires, but hardware palpability, technical risks of cortical drilling, postoperative alopecia and poor reliability prompted the development of bioabsorbable brow fixation devices [75, 76]. In 1996, Pakkanen and coworkers described their biodegradable polylactide pericranial pins and several similar devices have since emerged [77].

Benito et al. found fixation with bioabsorbable polylactic acid copolymer screws gave equivalent outcomes and fewer complications compared to stainless steel screws in their study of 99 patients [78]. Polylactic acid tacks reportedly gave satisfactory results in fifty patients, albeit with a mean follow-up of only five months [79].

The bioabsorbable Endotine device, a polylactide homopolymer, was first described in 2003 by Stevens et al. in a series of nine patients, which showed that the device provided rapid and secure fixation with apparently fewer complications than other fixation techniques, but was still palpable at six months [80].

Chowdhury et al. reported their experiences with the Endotine device in 31 patients [81]. They achieved a mean brow lift of 2.8mm, with no recurrences up to 22 months [81]. The problems they encountered were palpability, tenderness and numbness, visible lumps, device mobility and exacerbation of a high hairline [81].

However, patient satisfaction was high, with 95% of patients self-reporting as 'happy' or 'very happy' and 81% saying they would recommend Endotine fixation to others [81].

Table 8. Summary of different brow fixation techniques from published case series

Series	n	Fixation method	Mean follow-up (yrs)	Brow elevation at last follow-up (mm)	Complications, comments
McKinney and Sweis 2001 [27]	93	Bone tunnels and absorbable suture	5	4	No relapses
Jones and Grover 2004 [62]	349	PDS and bone tunnels	0.75	6.16	
Jones and Grover 2004 [62]	189	Fibrin glue	0.75	3.79	1 revision for relapse
Foustanos et al. 2006 [71]	300	Absorbable subperiosteal suture	4	Not stated	No recurrences
Tuccillo et al. 2007 [46]	32	Galeal/periosteal flap imbrication	1.25	5 (lateral)	Partial relapse in 5 patients
Chowdhury et al. 2007 [81]	31	Endotine	2	2.8	No relapses
Honig et al. 2008 [82]	25	Cortical bone tunnels	1	3 (lateral)	2mm relapse between 6 and 12 months
Honig et al. 2008 [82]	22	Endotine	1	4 (lateral)	2mm relapse between 6 and 12 months

In a case controlled study of 47 patients by Hönig et al., the Endotine device was compared to conventional single point tissue fixation with sutures anchoring the galea and periosteum to cortical bone tunnels [82]. In both groups the lateral brow position became depressed in the first six months after surgery but the medial third position was better maintained with the Endotine device, although this was not statistically significant [82]. Pascali et al. maintain that lateral brow ptosis and temporal laxity correction is difficult with the Endotine device and therefore trialled the so-called Endotine Ribbon™ (Coapt Systems), a flexible polylactic acid ribbon with multi-point fixation [83]. They reported ‘satisfactory’ lateral brow lifting in a case series of thirty patients using this new device [83]. Problems of persistent palpability and sensitivity with the Endotine prompted fabrication of the Ultratine using a second-generation polymer, polylactic acid and polyglycolic acid that dissolves more quickly [84].

Brow elevations achieved with different fixation techniques are summarised in Table 8. The studies have varying durations of follow-up and methods of measuring brow elevation, so it is impossible to assign superiority to any technique.

A prospective randomised controlled trial with long-term follow-up would address this question but could prove practically challenging.

Nonetheless, the Endotine device seems to be as effective as any other and has grown in popularity because of its combination of multi-point fixation, cortical attachment and slow absorption.

Variations of Endoscopic Brow Lift

Three variations of the EBL deserve brief mention for their ingenuity although they are not routinely practised - the transblepharoplasty EBL, the extended EBL and EBL combined

with the CO₂ laser. In 1996 Ramirez described the transblepharoplasty forehead lift in fourteen patients, achieving upper face rejuvenation solely via upper blepharoplasty incisions with the use of an endoscope [85]. Its application is limited to patients with male pattern baldness, high foreheads and relatively mild lateral brow ptosis who are also having simultaneous upper blepharoplasties. In a subsequent case series of 43 patients lateral brow elevation was maintained in 36 patients for up to seven years [86].

Byrd described the extended brow lift, using an endoscope to dissect into the midface to reposition the orbital orbicularis oculi, malar fat pad and nasolabial folds [65]. Satisfactory aesthetic results were reported in 42 patients over six to eighteen months follow-up, although no methodology was given for this assessment [65]. There was one case of transient frontal branch palsy [65]. Ramirez took the concept further to include subperiosteal endoscopic dissection of the central oval of the face to give a 'tridimensional' endoscopic rejuvenation which, in his series of 500 patients, produced excellent aesthetic results with minimal sequelae or complications [87].

Eight case controlled studies and case series were published in the 1990s advocating simultaneous EBL and laser resurfacing but discussion is notably absent in the literature since then. The rationale is that the CO₂ laser can target the deep vertical and transverse forehead rhytids that EBL can't address. Several small series claim low complication rates and good aesthetic results although with little objective assessment [88, 89]. In the biggest case controlled study of 174 patients, Roberts and Yokoo found signs of periorbital ageing such as altered pigmentation and crow's feet were improved in the EBL plus laser resurfacing group but not in the OBL without laser resurfacing group [90]. Although low complication rates are quoted in these papers, the lack of uptake of this procedure suggests that the risks of flap necrosis, poor scarring, prolonged erythema and additional costs have dissuaded most practitioners.

OPEN VERSUS ENDOSCOPIC BROW LIFT

A survey in 2001 by Elkwood et al., completed by almost 600 members of the American Society of Plastic Surgeons (ASPS) and representing data on almost 7,000 brow lifts, addressed the aesthetic outcomes, longevity of effects and the incidence and severity of complications for OBL and EBL [91]. The two types of brow lift were performed in similar numbers and patient satisfaction was over 98% for both procedures. Surgeons found OBL to be more effective in terms of brow elevation, reduction of transverse rhytids and glabellar lines (Figure 3) [91].

Other studies appear to favour EBL over OBL. A retrospective comparison of 120 patients having either procedure found that one year after OBL there was no significant difference from the preoperative brow position, whereas the brow was seven millimetres higher in the EBL group [41].

With an open approach division of cutaneous sensory nerves is inevitable and one would expect better preservation of scalp sensation in EBL at least in the short term. In a prospective, non-randomised controlled comparative study of eleven patients undergoing EBL versus ten undergoing OBL, both demonstrated subjectively and objectively decreased scalp sensibility postoperatively. However, compared to the EBL group the OBL group

showed significantly less scalp sensibility up to fourteen weeks, although by 24-26 weeks there was no difference [92]. Sensation was measured objectively (mechanoceptive and thermoceptive) and subjectively (visual analog scale).

Rating scale is 0 (not efficacious) to 5 (fully attaining aesthetic goals) [91].

Figure 3. Aesthetic results of OBL versus EBL according to a survey of 600 ASPS surgeons (7000 brow lifts).

Of 58 patients who were retrospectively enrolled in the same study, scalp sensitivity was reduced in all but significantly more so in the OBL group between six and eighteen months, with the difference disappearing beyond this point [92]. Interestingly, 57 of the 58 patients found that their scalp numbness was bad enough to deter them from undergoing the surgery again regardless of the technique of brow lift used [92].

Complication rates, efficacy and patient satisfaction data presented in case series of both OBL and EBL are summarised in Tables 9, 10 and 11. Although not a formal meta-analysis, the total number of patients represented is 5500 and two thirds of series have over eighteen months follow-up. Few studies include objective measures of brow lift in terms of absolute brow elevation or reduction in rhytids. Results are frequently in the form of subjective assessments by surgeons and patients making it difficult to compare one study with another. As the number of empty boxes illustrate, it is difficult to extract a complete set of comparative complication rates from each series and typically references to complications are brief and lacking in raw data. Furthermore, the definitions of the different complications are inconsistent, particularly in relation to dysaesthesia and alopecia and whether they are transient or permanent. Nonetheless, the figures suggest similar complication rates for both procedures with neither appearing strikingly superior.

Figure 4. The complication rates of OBL versus EBL from a survey of 600 ASPS surgeons [91].

It is difficult to determine from the literature which procedure has greater efficacy (Table 10) or patient satisfaction (Table 11). A minority of studies objectively assess aesthetic results whereas the majority claim very high patient satisfaction without describing how this was ascertained or giving figures. Those few studies that do compare OBL and EBL have found little difference in aesthetic results. Tabatabai and Spinelli retrospectively compared their limited incision OBL (93 patients) with EBL (100 patients) with up to five years follow-up [93]. No significant difference was found in average brow elevation between the two groups (four millimetres). Patient satisfaction was equivalent in both groups although the figures are not given [93]. A retrospective comparison of 84 patients undergoing either coronal, trichophytic or endoscopic brow lifts did not find a statistical difference in elevation at nineteen months follow-up (3.5, 3.4 and 3.2mm respectively) [94]. The brows in all groups maintained elevation at long-term follow-up (35 to 56 months) with no statistically significant difference between them [94].

In Guyuron and Rowe's series of 755 patients, 438 had endoscopic forehead lifts, 297 had pretrichial lifts and twenty had major scalp advancements [31]. Complications were remarkably rare, the commonest being delayed healing (2.2% in the OBL group) with no permanent dysaesthesias. Successful forehead rejuvenation was apparently achieved in both groups but no data is given to support this assertion [31]. Dayan et al. compared endoscopic and coronal approach brow lifts in a 140-patient case comparative study, with 121 patients having OBL versus nineteen EBLs and found no significant difference between the groups in postoperative brow position at twelve months [95]. Elkwood's survey of 600 ASPS surgeons suggests that the complication rate is equally low for either procedure, the most frequent complication in both being alopecia (Figure 4) [91]. However, these figures rely on surgeon recall rather than rigorous assessment of medical records or prospective data entry and are therefore subject to recall bias. Supporting this, the rate of permanent sensory loss in the OBL group was unusually low at 0.07% [91].

A meta-analysis of fifteen well designed studies selected from 189 articles concluded that there was no clear evidence indicating superiority of either technique in terms of brow elevation or complication rates [96].

As with many other aesthetic procedures the truth may be that OBL and EBL are both superior for different patient groups. Guyuron and Rowe select OBL or EBL according to the height of the forehead, recommending EBL for those with mild elongation, OBL for moderate elongation and open forehead shortening using a pretrichial incision for those with severe forehead elongation [3].

Table 9. Complication rates from case series of open and endoscopic brow lifts

CONCLUSION

The published literature regarding brow lifting is mainly in the form of case series (level IV) and ranges from level V to level II evidence. The anatomy of the brow has been well elucidated and is fairly constant. Both OBL and EBL reliably elevate the brow for at least 24 months. However there is a gradual loss of effect with time and no evidence that either procedure has greater efficacy. Both procedures have equivalent low complication rates and are associated with very high patient satisfaction. There is no proven superiority of one incision or plane of dissection in OBL or one method of cranial suspension in EBL.

In short, brow lift is a relatively safe and modestly effective procedure with several variations that can be tailored to suit different patients.

Chapter 31

BLEPHAROPLASTY

Mano Sira*

Western Eye Hospital, Imperial College NHS Trust, London

KEY POINTS

- Consider eyebrow and eyelid position to plan appropriate adjunctive procedures such as brow lift or ptosis repair.
- Address risk factors for dry eye. Evidence supports the use of omega 3 and phytoestrogen supplements in dry eye.
- Skin incision using radiofrequency does not appear to offer any benefit compared with traditional knife incision.
- There is a trend towards orbital fat preservation rather than resection.
- Eyelid laxity must be avoided
- Consider the need for lateral canthal support.
- Lower eyelid swelling is more frequent in the transconjunctival approach to blepharoplasty.

INTRODUCTION

Blepharoplasty has been the subject of extensive publications in the surgical literature - a literature search for 'blepharoplasty' yields more than 2400 hits. This chapter therefore does not set out to be an exhaustive summary of the evidence base but rather addresses the main areas of concern encountered by the surgeon undertaking blepharoplasty surgery.

LITERATURE SEARCH

A comprehensive review of the blepharoplasty literature in 2013, including PubMed, the Cochrane Library, EMBASE and CINAHL reveals that most publications are of level IV and V evidence (Appendix), with a lack of high quality Level I or II evidence.

In evaluating the current best available evidence the following terms were combined as appropriate: blepharoplasty; upper eyelid; lower eyelid; Asian; surgery; technique; preoperative assessment; postoperative; individual complications (including the terms dry eye, haematoma, blindness, ectropion, retraction, lid malposition, scleral show, scarring, chemosis, infection, inflammation, suture abscess, granuloma, post-blepharoplasty ptosis and lagophthalmos); outcomes; eyelid analgesia; and pain control/management. Medical Subject Headings (MeSH terms) were used if available, the search was limited to publications in English and additional references were included if appropriate.

AESTHETICS AND THE AGEING EYELID

There is no consensus on the perfect eyelid aesthetic since personal preference, racial differences and overall harmony of the facial subunits are very individual. The patient attending for upper periorbital rejuvenation may be offered brow lift surgery by one surgeon or upper blepharoplasty by another. There is inherent inconsistency because of the difficulty in determining to what degree each feature has changed. Obeying certain parameters, however, aids the surgeon in their surgical plan.

The following changes known to occur to the upper eyelid/periorbital area have an ageing effect on the appearance[1]:

Loss of volume due to thinning of the skin with associated fat and muscle atrophy. This often results in the deep upper eyelid sulcus seen in older patients.

A raised upper eyelid skin crease, increasing the pretarsal show. This is due, in part, to involutional ptosis and dehiscence of the levator aponeurosis and its insertion into the subdermal tissues, which create the crease.

The lateral brow/eyelid junction is convex with a gentle arc in youth (Figure 1), becoming less convex and flatter due to volume deflation and descent respectively [2] (Level V).

In the lower eyelid, rounding of the lateral canthal angle [3] (due to dehiscence of the lateral canthal tendon), lower eyelid laxity, orbital fat prolapse at the insertion of a lax orbicularis-retaining ligament and volume deflation of the malar region (SOOF) resulting in a tear trough/naso-jugal groove all contribute to an aged appearance.

Figure 1. The attractive youthful upper eyelid/brow junction exhibits a gentle convex arc.

THE ASIAN EYELID

Anatomy of the Asian versus Caucasian Eyelid

With the possible exception of the presence of an epicanthal fold, the lack of an upper eyelid skin crease is the most striking point of difference between the Asian and Caucasian upper lid. When present it is formed by the anterior insertion of levator aponeurosis fibres into the subdermal tissues the pretarsal skin and is most evident on eye opening when the lid is retracted. The skin that folds over the supratarsal crease is described as the double eyelid fold. The pretarsal skin visible just below the double eyelid fold is referred to as the pretarsal show.

Comparative studies between Asian and Caucasian upper eyelids show that the Asian single eyelid (with an absent or low crease) exhibits fusion of the orbital septum to the levator aponeurosis below the superior tarsal border, whereas this fusion is above the superior tarsal border in Caucasians (Figure 2). The preaponeurotic fat pad therefore descends anteriorly to the tarsal plate in the Asian single eyelid and a thick subcutaneous fat layer prevents levator fibres from extending toward the skin near the superior tarsal border. Structural differences relating to increased fat in the Asian upper eyelid include the presence of a pretarsal fat pad and a moderate fat increase in the double Asian eyelid [4] (Level III).

In contrast, cadaveric dissection by Kakizaki [5] (Level V) describes how the orbital septum attachment on the levator aponeurosis in Asians seems to be situated above the superior tarsal plate border *in vivo*, but the preaponeurotic fat extends beyond the distal end of the anterior layer of the levator aponeurosis (DEALLA), sometimes reaching the tarsal plate. The Asian upper eyelid crease is thus lower and less distinctly defined than in Caucasians due to the inferior extension of the preaponeurotic fat which can interrupt the superficially extending, skin crease defining, levator aponeurosis fibres. In addition the tarsal plate is shorter and pretarsal suborbicularis tissue is thicker in Asian than Caucasian upper eyelids.

Figure 2. Anatomy of the Asian upper eyelid, (after Kakizaki (5)).

Aesthetics of the Asian versus Caucasian Eyelid

An interesting study recently compared composite images created by digital morphing of faces from different racial origins to analyse contributors to faces being deemed average and attractive [6] (Level I). They discovered that attractive Korean faces have relatively wide-set eyes and that the medial and lateral eye fissure height (as measured at the midpoint of medial and lateral eye fissures, respectively) were greater than in average Korean faces. The median eye fissure height (palpebral fissure height vertically from pupillary centre) was also greater in attractive Asian faces than average Asian faces. Attractive Korean or Asian faces did not have an epicanthus and exhibited more exposure sclera in the medial and lateral area of the eyes. Attractive Asian faces had a less steeply slanted palpebral fissure compared to average Asian faces, but attractive Caucasian and African faces had a steeper palpebral than their average counterparts. Finally, attractive Caucasian and African faces had a relatively narrower palpebral fissure height and width than average Caucasian and African faces. Regardless of race, attractive faces had wide-set eyes and a lower brow position than average faces. These interesting observations might suggest that attractiveness occurs through some form of 'convergence to the ethnic mean', at least for some morphologic features, although the researchers did not explore this.

THE NEGATIVE VECTOR

The position of the globe relative to the orbital rim will affect the success of blepharoplasty. A constellation of features contributes to the 'morphologically prone eye' [7] (Figure 3). It is useful to exclude horizontal lid laxity with a preoperative 'snap test', since blepharoplasty carried out on a lax lower eyelid can result in inferior scleral show and/or ectropion. A negative vector, in which the apex of the cornea is anterior to the inferior orbital rim, can result in the lid slipping under the globe following blepharoplasty, thus worsening inferior scleral show. Patients with a negative vector orbit should be counselled of this risk and, should they wish to proceed, the addition of lateral canthopexy/canthoplasty is highly recommended [8] (Level III). The vertical height of the eyelid must also be taken into consideration [9] (Level V).

A negative vector can be a sign of maxillary hypoplasia. Associated features include inferior scleral show, prominent medial fat and a prominent nasojugal crease. Pessa et al. [11] (Level III) showed that the craniofacial skeleton remodels throughout adulthood, the orbital rim moving posteriorly relative to the anterior cornea with advancing age. Thus over-resection of orbital fat during lower blepharoplasty can emphasise the relative proptotic appearance of the eye that occurs naturally with age due to orbital remodelling. Pessa et al. also found that with age there is a tendency for the cheek mass to move posteriorly relative to the corneal apex (see Chapter 32).

Figure 3. Morphological classification of globe/bony orbit relationships and corresponding exophthalmometry measurements (in millimetres). Data from Hirmand et al.[10].

AVOIDING THE DRY EYE

Peri-operative and postoperative complications can be minimised by recognising and addressing the following risk factors: refractive corneal surgery [12] (Level IV); diabetes [13] (Level V); smoking [14] (Level II); previous eyelid surgery; bleeding disorders and anti-coagulant use, preoperative brow position [15] (Level III), ptosis, the presence or absence of an upgoing Bell's reflex and orbicularis oculi function (i.e., lagophthalmos).

Hamawy and coworkers [16] (Level III) retrospectively examined 202 patients undergoing upper and/or lower blepharoplasty and found dry eye persisted for over two weeks in 10% of patients. They provide an algorithm for preventing and managing dry eye.

The preoperative assessment should screen the patient for symptoms of dry eye, such as burning, itching, a foreign body sensation, watering, aching and generally tired eyes. If these

symptoms are made worse by activities of reduced blinking such as computer use or long periods of reading, the patient is likely to have evaporative dry eye.

Reduced tear break up time (TBUT) is a good indicator of evaporative dry eye and is improved with oral omega-3 supplementation. In their double masked study Kangari and colleagues [17] (Level I) randomised 64 patients into two groups, receiving either placebo (two medium-chain triglyceride oil capsules daily) or omega-3 (one capsule of each of 180mg eicosapentaenoic acid (EPA) and 120mg docosahexaenoic acid (DHA) daily) for thirty days in each case. Repeated-measures analysis of variance showed that improvements in TBUT, Ocular Surface Disease Index (OSDI), and Schirmer's scores were significantly better in the treatment than the placebo group.

Signs and symptoms of dry eye syndrome can also be improved by phytoestrogen supplementation in postmenopausal women [18] (Level I) recruited 66 postmenopausal women, all with low sex hormone levels correlated with high tear film osmolarity values, in their double-masked cross-over placebo study. Subjects were randomised into two study groups receiving either phytoestrogen or placebo. After thirty days of therapy, assessment of Schirmer test and TBUT showed the treatment group had significantly decreased tear osmolarity and increased tear production compared with the placebo group.

Whilst high level evidence does not exist, there is expert opinion and surgical consensus that patients who have undergone corneal refractive surgical correction should wait at least six months before undergoing blepharoplasty, chiefly because of the effects on corneal sensation, tear production and tear film alteration [19] (Level V).

AMOUNT OF SKIN EXCISION

The degree of skin excision in blepharoplasty should be tailored to the individual, for instance using the popular skin pinch method [20, 21] (Level IV). Halvorson et al. [22] (Level III) describe the pinch technique used in 476 patients over ten years (Figure 4): a line is drawn at 45° from the medial and lateral ends of the supratarsal crease ending 6mm from the angular vein of the nose (visible as a blue line) and 12mm from the lateral palpebral fissure respectively. The inferior marking follows the existing or desired supratarsal crease (typically 8-10mm above the lid margin) and the superior marking is based on the skin excision determined by the pinch test, keeping at least 10mm from the infrabrow supratarsal eyelid skin.

TRANSCUTANEOUS V TRANSCONJUNCTIVAL APPROACHES

Taban et al. [23] (Level IV) retrospectively compared twenty patients (forty eyes) with 25 patients (fifty eyes), undergoing transconjunctival lower eyelid blepharoplasty with and without skin pinch (as described by Parkes et al. [24]) respectively. They concluded that the pinch method of skin excision minimises the risk of postoperative eyelid malposition by avoiding violation of orbital septum and orbicularis muscle. When lower blepharoplasty requires both fat and skin excision, the skin pinch technique with transconjunctival fat excision allows for stable postoperative lower eyelid position.

Figure 4. Skin markings for upper blepharoplasty. The incision starts medially 6mm from the angular vein and ends laterally 12mm from the palpebral fissure. At each end, incisions are extended superiorly at a 45° angle. After Halvorson [22].

Netscher et al. [25] (Level II) performed a non-randomised study on lower lid blepharoplasty via transcutaneous and transconjunctival approaches on the left and right eyelids respectively in ten consecutive patients. The authors commented that patients had predominantly lower lid fat problems with little or no skin excess. Outcome measures included standardised photographic evaluation by independent masked observers assessing for differences in scleral show, visible scarring, swelling or ectropion. Subjective patient evaluation was also carried out by questionnaire. There were no significant differences in aesthetic outcome and patient acceptance was equal between the two techniques. Transient lower lid swelling was more likely in the transconjunctival group but scleral show occurred with equal frequency and severity between the groups. External scarring using the transcutaneous technique was not a perceived problem in the subjective patient assessment and was not statistically different between the techniques as determined by photographic analysis.

ORBICULARIS MUSCLE RESECTION

Damasceno et al. [26] (Level II) compared pinch upper blepharoplasty with or without orbicularis excision (the muscle resection being equivalent to the amount of skin removed) in a randomised, double-masked, left-right study of fifteen consecutive female patients. Patients scored differences in oedema, haematoma, itching and pain between both sides on the seventh, thirteenth and nineteenth days and three masked oculoplastic surgeons analysed aesthetic outcomes using a visual analogue scale. They concluded that upper blepharoplasty causes more postoperative symptoms and presents worse initial aesthetic outcome when the preseptal orbicularis oculi muscle is excised, but the final aesthetic outcome is the same

whether preseptal orbicularis oculi is excised or preserved. However, the small study may have lacked the statistical power to detect a modest, but potentially significant, difference in outcome.

CREATING A DOUBLE EYELID CREASE

The creation of a 'double eyelid' is one of the most commonly requested cosmetic procedures in East and Southeastern Asian countries [27]. There are essentially two methods of creating an upper eyelid fold - the incisional fixation technique and the non-incisional suture method.

There is little evidence to guide selection of the surgical technique. The incisional method has been well described in the literature (Park and Park [27] (Level V)). The upper lid is everted and a caliper used to measure the vertical height of the central portion of the tarsal plate, which is usually 6.5 to 7.5mm in Asians. The lid is returned to its normal position and a mark is made at the central point of the crease incision at a height corresponding to that of the tarsus. If the crease shape chosen was a nasally tapered crease, the crease marking is merged toward the medial canthus. For a parallel crease shape design, the surgeon should make a conscious effort to stay parallel to the lash line as the mark approaches the medial canthus. A second line that demarcates the superior incision is made two millimetres above the inferior mark centrally, 2.5mm laterally, and one millimetre medially where the two lines converge [28, 29] (Level IV and Level V).

Following the skin crease incision, the orbital septum is opened over the preaponeurotic fat pad in order to avoid damage to the levator aponeurosis and muscle. A 6/0 or 7/0 nylon suture is then passed through the edge of the strip of pretarsal orbicularis from the under surface of the muscle and engaging the distal edge of the levator aponeurosis. The suture is tightened just enough to approximate muscle and aponeurosis without strangulation of the tissues. The fixation point in the levator aponeurosis determines the tightness of the pretarsal skin and the height of the supratarsal crease. This technique can elevate the upper eyelid (by effectively plicating the levator aponeurosis) thus widening the palpebral aperture.

LATERAL CANTHAL SUPPORT

Horizontal lower eyelid laxity is a significant cause of post-blepharoplasty lower eyelid ectropion/retraction. Whilst eyelid laxity is often obvious preoperatively, sometimes it is sub clinical and diagnosed retrospectively. In recent years routine lateral canthal support has been advocated to reduce the incidence of post-blepharoplasty lower eyelid malposition. Codner et al. [30] (Level III) reviewed 264 patients undergoing lower blepharoplasty with routine lateral canthal support (canthopexy, canthoplasty or orbicularis suspension, Figure 7) over a ten-year period. Lid malposition requiring correction occurred in 3.5% of cases compared to rates of between 5-30% in standard lower blepharoplasty. The authors conclude that this technique allows more aggressive tightening of the anterior lamella whilst preserving the preoperative eye shape.

Despite this conclusion, there appear to be situations in which additional lateral canthal support can worsen unwanted post-blepharoplasty sequelae, such as inferior scleral show in cases of prominent globes in the negative vector configuration. Goldberg [9] (Level V) provides reasoned argument for an individualised approach to providing lateral canthal support. Whilst lateral canthopexy/horizontal eyelid shortening has a powerful role where there is lower eyelid laxity, it will not elevate the eyelid in cases of postoperative (iatrogenic) vertical shortening of the lower eyelid, and can in fact worsen the situation.

MANAGEMENT OF ORBITAL FAT

Recent years have seen a paradigm shift in lower lid blepharoplasty with regards the management of orbital fat, favouring fat preservation rather than resection of prolapsed intraorbital fat. In his series of 152 patients Hamra [31] (Level IV) described a method of repositioning subseptal fat beyond the infraorbital rim and under the repositioned orbicularis muscle.

Parsa et al. [32] (Level III) provide long-term (mean 11.3 years, range 1-16) follow up data in 26 patients comparing fat removal with preservation using the technique first described by de la Plaza [33] (Level V), in which capsulopalpebral fascia is approximated to the arcus marginalis after repositing the herniated fat to the infraorbital compartment. Outcome measures assessed by the operating surgeon were time to palpebral bag recurrence, lower lid hollowing, lid malposition and eyelid dysmobility. The author concluded that fat preservation resulted in significantly less recurrence of palpebral bags (7.7% in the fat preservation group versus 30% in the fat removal group) [32].

SKIN INCISION AND CLOSURE

Skin incision and closure have been addressed by robust studies. Kashkouli et al. [34] (Level I) randomised 46 eyelids to compare eyelid skin incisions made with a scalpel in one eyelid versus a radiofrequency (RF) device in the other. Around six months postoperatively a masked observer assessed scarring using a visual analogue scale and a Cochet-Bonnet filament-type aesthesiometer, finding no significant difference in scar appearance or sensory recovery. The zone and depth of tissue damage on histopathologic examination was higher in the radio-frequency group but this did not appear to be clinically significant.]

**Table 1. Visual analogue scale for blepharoplasty scar assessment:
0 (best) to 10 (worst), from Kashkouli [34])**

	A. Colour	B. Surface	C. Contour	D. Distortion	E. Texture
1	Perfect	Matte	Flush	None	Normal
2	Slight mismatch	Shiny	Slightly proud/indented	Mild	Just palpable
3	Obvious mismatch		Hypertrophy	Moderate	Firm
4	Gross mismatch		Keloid	Severe	Hard

Kouba et al. [35] (Level I) conducted a randomised, split-eyelid, single-masked, prospective study comparing the efficacy of 6/0 polypropylene, 6/0 fast-absorbing gut, and ethylcyanoacrylate (ECA) tissue adhesive on 36 consecutive upper lid blepharoplasties. Patients' subjective outcomes of closure technique and cosmetic evaluation (thickness, width, texture, colour change, overall cosmetic outcome) were assessed at one and three months. Objective outcomes (cosmetic outcome of wound closure technique using standardised photographs) were assessed by a masked physician. Scoring was performed on a scale of one (excellent wound healing, scar matches surrounding skin) to five (poor scar wound healing, does not match surrounding skin). The researchers concluded that sutured epidermal closure and tissue adhesive are highly efficacious for upper eyelid blepharoplasty but that cosmesis using ECA was superior to that of fast-absorbing gut by three months after surgery - although the result did not reach statistical significance.

Greene et al. [36] (Level I) performed a prospective, randomised, single-masked study in twenty subjects (forty eyelids) undergoing upper eyelid blepharoplasty, closing one eyelid with octyl-2-cyanoacrylate and the other with suture. In contrast to the study of Kouba [35] and coworkers they found no difference in final incision appearance by four weeks after surgery, and also found wound complications and duration of healing to be similar. Whilst Kouba et al. [35] felt that tissue adhesive improved cosmesis compared with absorbable suture material over short and intermediate term follow-up, they did not find any advantage of tissue adhesive over non-absorbable (polypropylene) sutures. The evidence provided by the two randomised studies therefore shows no clear advantage of either closure technique overall.

LACRIMAL GLAND PROLAPSE

Massry [37] (Level III) reports the incidence of lacrimal gland prolapse in 57 patients with an average age of 78 years to be 60% after a mean follow up of twelve months. The author repositioned the prolapsed gland by suturing its anterior capsule to the arcus marginalis (just anterior to the lacrimal gland fossa) with 4/0 prolene suture. Six patients required further lacrimal gland suture repositioning due to prolonged swelling and three required suture repositioning of the lacrimal gland due to pain. This prospective study was undertaken in cases of functional blepharoplasty but may have application in cosmetic practice.

COMPLICATIONS

Lower Eyelid Retraction

Various methods exist to correct lower eyelid retraction following blepharoplasty. Simon et al. [38] (Level III) reviewed 43 cases of subperiosteal midface lift with and without hard palate grafts to correct lower eyelid retraction related to previous blepharoplasty or thyroid eye disease. They found that the addition of hard palate grafts was superior, reducing the inferior marginal distance by 2.2mm compared with 1.1mm without hard palate graft.

A technique that permits smaller degrees of elevation of a retracted lower eyelid without the need for grafted tissue has been described [39] (Level III). This involves preseptal/suborbicularis dissection and release of the orbito-malar ligament followed by recession of the septum and inferior lower eyelid retractors as a composite. The mean elevation in lower eyelid height in 26 eyes was 1.4mm.

Swelling & Bruising

Reducing oedema and bruising has been attempted by introducing autologous platelet concentrate in to eyelid incisions. In a prospective, randomised, controlled trial [40] (Level II). Thirty-three patients received autologous platelet concentrate in the eyelid incisions of one side during bilateral blepharoplasty surgery (either upper, lower or four lid blepharoplasty). The untreated contralateral eye was used as a control and did not receive any placebo treatment. Platelet-rich plasma was mixed with thrombin and applied topically to the wound on a randomly selected side before wound closure. Patients were examined and completed a questionnaire at postoperative days one, three, seven and thirty. A masked oculoplastic surgeon assessed photographs for bruising and oedema. Patients reported a statistically significant decrease in oedema at thirty days compared to the untreated eye. There was subjective reduction in bruising on the treated side although this difference was not statistically significant.

Retrobulbar Haematoma

Complications of blepharoplasty include haematoma which, if retrobulbar, can be sight threatening due to optic nerve compression [41] (Level V). Acute management involves immediate lateral canthotomy and intravenous steroid to relieve intraorbital pressure and inflammation. This is supported by widespread clinical experience, and the lack of high quality evidence is more a feature of an ethical inability to design a study around this than representing any doubt as to proper clinical management.

Chemosis

Chemosis due to dessication of pouting conjunctiva, can be treated with lubrication, topical steroid preparations, ocular decongestants, direct pressure and temporary tarsorrhaphy [42] (Level IV). Again, this is poorly supported by high level evidence but is considered standard practice.

Other

Pacella and Codner [43] and Hartstein and Kikkawa [44] provide excellent review articles of complications and their management following blepharoplasty.

CONCLUSION

The evidence base for blepharoplasty surgery is limited mainly to studies of Level III and below.

As for any surgery, meticulous patient selection and thorough preoperative assessment minimises postoperative complications. Particular attention should be paid to the brow and eyelid position so that adjunctive surgery such as brow lift or ptosis repair can be considered. Eyelid laxity should be identified and routine lateral canthal support has been advocated but remains contentious (Level III). Risk factors for dry eye should be addressed (Level III). Omega 3 and phytoestrogen supplements have high levels of evidence supporting their use in dry eye (Level I). There is no evidence comparing skin pinch excision techniques versus measured skin excision and both methods appear equally effective (Level III, IV). Similarly transconjunctival and transcutaneous approaches to lower blepharoplasty are both efficacious but lower lid swelling is more frequent after the transconjunctival approach. Transcutaneous techniques are not a perceived problem in terms of subjective scarring (Level II). There is an increasing tendency towards orbital fat preservation rather than resection during blepharoplasty (Level III). Skin incision with radiofrequency is no better than cold steel (Level I) but scar cosmesis may be superior with tissue adhesives compared with resorbable sutures (Level I). Excising preseptal orbicularis oculi muscle when performing upper blepharoplasty causes more postoperative symptoms and presents worse initial aesthetic outcome, but the final aesthetic outcome is the same whether the muscle is excised or preserved (Level II). Finally in cases of persistent postoperative lower eyelid retraction, the use of hard palate grafts as a spacer should be considered unless very modest elevation is required (Level III).

Chapter 32

FACELIFT

Fulvio Urso-Baiarda^{1,*} and Rajiv Grover²

¹Wexham Park Hospital, Slough, UK

²King Edward VII's Hospital Sister Agnes, London, UK

KEY POINTS

- There is no clear evidence that one face-lift technique is significantly better than any other.
- Preinfiltration is carried out almost unanimously, but the composition of infiltrate has not been subjected to rigorous investigation and remains a matter for debate, although there is some evidence that the omission of adrenaline may reduce the rate of postoperative haematoma.
- Fibrin tissue adhesives may confer some benefit, mostly in terms of bruising and swelling, but the clinical importance of such benefit is debatable, particularly when considered against cost and the risk of transmissible disease.
- The benefit of suction drains is most probably similarly minor, but the risk-benefit balance is more favourable owing to their low cost with no increased risk of disease transmission.
- The overall published haematoma rate following face-lift is around 3.5%, but the risk is much greater if surgery is combined with anterior platysmaplasty or if the patient is male, smokes, takes blood-thinning agents or has uncontrolled hypertension. Smoking also risks vascular compromise and wound impair men.

INTRODUCTION

The face is the major focus of social encounters, second to none. It projects a first impression to the outside world of our character, health, energy, vigour and youthfulness. The

* Corresponding Author's Email: fulvio@doctors.org.uk.

desire for that impression to be positive is reflected in an unremitting demand for facial rejuvenation.

In a very early account of facial cosmetic surgery, Pangman and Wallace [1] expressed their opinion that:

“there is no field which requires more exacting technique, more highly developed esthetic sense, greater human understanding, and which causes more trial and tribulation than does cosmetic surgery”.

The procedures offering to achieve a patient's aims are myriad and can be baffling – not just to the patient. By way of a background to understanding the contemporary techniques in use, this chapter shall describe some of the changes that take place in the ageing face, provide a historical account of the techniques that have arisen to deal with them, and consider the relevant refinements in our anatomical understanding of the region. This is followed by consideration of the currently available evidence on technique selection, efficacy and longevity, as well as the development and avoidance of complications.

HOW DOES THE FACE AGE?

The classic description of changes taking place in the ageing face was provided by Gonzalez-Ulloa [2], based on observations of the relationships between various soft tissue landmarks correlated with radiographic views of the underlying skeleton. This was in broad agreement with Pitanguy's [3] later quantification of ageing changes in women. Quantitative comparison of patients with historical photographs by Yousif and colleagues [4] revealed a progressive deepening of the nasolabial fold accompanied by inferior, lateral and anterior migration of the soft tissues of the cheek, the latter most likely causing the former [5].

Whilst descent undoubtedly does take place in the ageing face, other authors place greater emphasis on the contributions of progressive soft tissue and skeletal deflation. Pessa [6] used three-dimensional stereolithography and laser polymerization modelling of the facial skeletons of twelve young and old men to analyse ageing skeletal changes, concluding that the facial skeleton continues to grow during adulthood and facial structures rotate downward and inward with respect to the cranial base. The author speculated that such changes may be responsible for some well-recognised stigmata of ageing – the tear trough deformity [7] and the negative vector orbit [8].

Little9 echoes such views in his summary of the features of youth and ageing (Figure 1). In his view, facial ageing occurs gradually as a transition from a heart to rectangular to pear-shaped face, due to gradual soft-tissue descent. Rejuvenation is therefore best achieved by redistribution rather than excision of tissues. Perhaps surprisingly, the same study has not been carried out in men, in whom a rectangular face does not appear stigmatic of ageing but can be consistent with rugged youthfulness. A tendency towards squaring off of the lower face in either gender could be responsible for the occasionally stated impression that 'men age better than women'.

Figure 1. Features of an aged versus a youthful face orbit and mouth. Adapted From Little (2000).

On a histological level, skin creases can result from a number of different mechanisms [10]. Wrinkles can be considered dynamic or static, resulting respectively from the effect of muscle insertions or from intrinsic skin changes, such as elastosis and epidermal atrophy combined with the progressive effects of gravity. Light and electronic microscopic study has failed to reveal any consistent structural change associated with wrinkles, and Kligman and colleagues [11] concluded that they are a mechanical phenomenon taking place in areas of mobility. Subsequent similar analysis revealed elastotic swelling on either side of a wrinkle – thus the wrinkle itself may represent a strip of normal tissue within a region of swollen dermis [10]. In support of this, Chatterjee's [12] study of wrinkling in the UVB-radiated hairless mouse concluded that elastosis-associated skin swelling combined with reducing collagen content permitted a fracture in the dermal collagen layer in response to mechanical trauma. One may speculate that stretch marks could result from a similar process subjected to tension rather than flexion.

CHANGING PRIORITIES FOR FACIAL REJUVENATION

Aims of facial rejuvenation have evolved with improved understanding of the ageing processes in the face and refinements in concepts of beauty. Developments in surgical

technique have broadly mirrored those developments. Thus a preoccupation with effacement of nasolabial and labiomandibular folds has given way to correction of both tissue atrophy and downward migration. Some previously observed sequelae of ageing – jowls, deepened nasolabial folds – are now conceptualised as shelving of descending soft tissues over fixed areas, therefore representing a need for resuspension rather than a large wrinkle in need of flattening.

In his analysis of ageing changes in the face and strategies for effective rejuvenation, Little [9] lists his order of priorities as: first, restoration of the facial ogee; second, periorbital and perioral improvement; and third, nasolabial fold effacement. This reverses the common primacy of nasolabial fold obliteration as a key end point in facial rejuvenation. The ogee is an architectural term referring to two opposing sigmoid forms, a very common aesthetic detail (Figure 2). Little observes that a correctly aligned oblique facial photograph shows an ogee with a zygomatic peak in youth but not in senescence, attributing this to tissue atrophy and descent, and identifying its restoration as critical to rejuvenation [9].

There are several interesting consequences of a model of ageing by soft tissue atrophy and descent. Firstly, in the mid and lower face, changes are both additive and subtractive, whereas in the neck they are purely additive. Little believes this partly accounts for the success of the reductive surgical techniques in use (liposuction, platysma retensioning) to rejuvenate the neck but failure of such techniques to rejuvenate the upper midface. Since atrophy is a continuing process, fat stores should be preserved and redistributed rather than excised where possible [9].

Figure 2. The ogee is an architectural form consisting of two opposing arcs. The youthful facial ogee is evident in oblique view, and its loss is perceived as unattractive.

Another consequence of a volumetric model of facial ageing is to render tension-based rejuvenation strategies conceptually flawed, since tension across a deformable tissue will flatten it. An unnatural ‘windswept’ appearance can be a consequence of a purely tension-based rejuvenation strategy:

“excessive tension on deformable tissues... produces an appearance of tightness, an attribute that occurs in neither the aged nor the youthful face, but only in the postsurgical face.”[9]

IMPORTANT ANATOMICAL CONCEPTS

The Superficial Musculo Aponeurotic System (SMAS)

At the direction of their tutor Paul Tessier, who was aware of Tord Skoog having used a combined flap of skin and a subcutaneous fascial structure, Mitz & Peyronie [13] provided the first detailed description of the SMAS in their landmark paper. The description of SMAS, as an investing layer for mimetic muscles, continuous inferiorly with platysma and superiorly with superficial temporal fascia, lead the way to face-lift procedures based on SMAS dissection. Use of SMAS is associated with two main benefits - avoidance of excessive skin tension by basing midfacial resuspension on the SMAS layer; and permitting different vectors of closure of skin and SMAS flaps. Comparisons of the biomechanical properties of dermis and SMAS excised during face-lift indicate that SMAS exhibits less stress relaxation and creep [14,15]. These observations would explain clinical observations of improved longevity of SMAS-based face-lifts.

Mitz & Peyronie also described important relations between SMAS and nerves in the region - crucially, that motor nerve branches run deep to it and only sensory branches superficial. Although this formal description of SMAS came somewhat late historically – after, for instance, the Skoog face-lift which appeared to make use of it – a superficial fascia of the face was referred to much earlier in Gray’s Anatomy of the Human Body (1859) [16].

Retaining Ligaments of the Face

Furnas [17] described areas of adhesion, or “ligaments”, between the dermis and the skeleton at the zygoma and mandible, and fibrous connections from platysma to dermis (Figure 3). Their description was accompanied by the realisation that ligament release was crucial for facial rejuvenation to transmit force exerted through SMAS tension more distantly, and was subsequently incorporated into various forms of face-lift.

Stuzin, Baker and Gordon [18] described similar areas of dermal attachment to relatively fixed structures other than periosteum (parotid gland, anterior border of masseter).

Figure 3. Furnas described retaining ligaments of the cheek at the zygoma ('McGregor patch') and the mandible, plus two further condensations of platysma to dermis – the platysma-auricular ligament and the anterior platysma cutaneous ligament. (After Furnas 1989).

The Platysma

Cadaveric and clinical examinations of platysma demonstrate normal anatomic variability that could explain why certain ageing changes occur in some individuals and not others. A study of fourteen cadaveric and 21 clinical cases found demonstrated decussation of platysma across the midline in just under two thirds of cases, whereas in the remainder there were free medial edges [19]. These free edges can lead to platysma bands and permit submental fat pseudo herniation into the interval between them - the so-called 'turkey gobbler' deformity.

The Facial Nerve

Knowledge of the location of the facial nerve and its variations is central to safe face-lift surgery. A technique for preoperative percutaneous facial nerve mapping has been described²⁰ but has not become established in clinical practice, probably due to the additional operative time necessary. Most surgeons continue to rely on techniques based on operating in facial regions and planes which anatomical knowledge tells us do not contain branches of the facial nerve. The relationships of nerve branches to SMAS as described by Mitz and Peyronie is very useful in this regard¹³.

Following approximately two thousand facial nerve dissections for parotidectomy, Baker noted that frontal and mandibular divisions of the facial nerve are usually terminal, whereas

the remaining facial nerve divisions usually ramify widely and exhibit crossover communications [21]. Thus the functional consequences of frontal or mandibular nerve injury are likely to be more profound and less likely to recover. Other dissections have shown that the depth of the facial nerve at the anterior parotid is usually nine to ten millimetres below the skin surface [22].

The course of the frontal branch of the facial nerve is summarised in the classic paper of Pitanguy and Silveira Ramos [23] as approximating a line drawn from five millimetres below the tragus to fifteen millimetres above the lateral eyebrow (Figure 4). The important relationships of this branch to the temporal fascia were described by Stuzin and colleagues [24] as follows: the temporal fascia is arranged in three laminae, the temporoparietal fascia most superficially, and superficial and deep laminae of the deep temporal fascia. The frontal branch passes superiorly along the underside of the temporoparietal fascia. Thus the plane deep to the superficial lamina of the deep temporal fascia represents a safe dissection plane in this region. During a subcutaneous dissection in the temporal region, care must be taken not to penetrate superficial temporal fascia to avoid injury to the frontal branch of the facial nerve.

Figure 4. Location of the frontotemporal branch of the facial nerve. (Data from Pitanguy I, Silveira Ramos A: The frontal branch of the facial nerve: The importance of its variations in face-lifting. *Plast Reconstr Surg* 38:352, 1966.)

In the lateral cheek the buccal branches of the facial nerve are protected between superficial and deep lobes of the parotid gland, but anteriorly lie directly beneath a fragile layer of SMAS [13].

In a study of 100 dissections of the mandibular ramus of the facial nerve [25], laterally (posterior to the facial artery) the branch dipped as much as one centimetres below the edge of the mandible in almost one fifth of cases. Anterior to the facial artery the nerve was always above the lower border of mandible.

Cervical Sensory Nerves

The great auricular nerve is at risk during the postauricular and cervical dissection of face-lift procedures. To assist in its preservation, its course was delineated by McKinney and Katrana [26], who state it: a) crosses the belly of sternomastoid at its midpoint 6.5cm below the external auditory canal; and b) runs close to the external jugular vein just beneath the skin and SMAS. McKinney and Gottlieb [27] felt that the safest place to incise SMAS/platysma is immediately anterior to sternomastoid, where the great auricular nerve passes deep into the parotid. Izquierdo and colleagues [28] observed that its postauricular branches extend no further than 1.5cm posterior to the ear lobule, therefore recommending placement of mastoid tacking sutures more posterior than this.

The lesser occipital nerve can have greater significance during face-lift surgery than may be credited. Pantaloni and Sullivan [29] found that it innervated the superior third of the ear and mastoid in around sixty percent of cases, the superior two thirds of the ear in twenty percent of specimens, and almost the entire ear except the lobe in five percent. Although it usually travelled over sternomastoid fascia beneath SMAS, it sometimes ran subcutaneously, placing it at significant risk of division during face-lift. Patients should be counselled accordingly. We are not aware of studies demonstrating the frequency of a coexistent dominant (innervating most of the ear) and superficial (subcutaneous) lesser occipital nerve – the most concerning anatomical variation for those performing face-lifts that included a postauricular dissection.

FACE-LIFT TECHNIQUES

There have been three broad historical schools of thought regarding face-lift techniques. These are: face-lifts based exclusively on skin flaps; face-lifts based on skin flaps with manipulation of underlying SMAS, without SMAS dissection; and face-lifts in which skin and SMAS flaps are raised and mobilised independently. Within each group, evolution and modification has resulted in the current diversity of practice.

The earliest face-lifts were skin-only procedures. At simplest, these consisted of skin excision with direct closure. In the year of his death in 1932, Holländer described having performed a face-lift in Berlin on a Polish aristocrat in 1901. This was at her apparently determined insistence and following her "feminine persuasion" [30]. She presented Holländer with a drawing showing that the removal of facial skin from in front of the ear would improve her nasolabial folds and elevate the corners of her mouth.

Although apparently successful, such techniques gave way to raising and redraping superficial skin flaps. Bettman can be credited in 1920 [31] both with publishing the first pre-

and postoperative photographs following face-lift surgery and with combining two separate (occipital and temporal) incisions into a single incision more similar to those in current use.

Skoog (1974) is usually credited with first raising and redraping skin and SMAS (termed 'superficial fascia') as a single unit [32], although there are similarities to the earlier account of Pangman and Wallace [1]. Skoog certainly popularised the approach, which represented a major advance by taking wound tension off the skin and transferring it to SMAS, hitched onto deep temporal fascia above the zygomatic arch. However, the midface correction achieved was probably limited by failure to release the zygomatic and upper masseteric retaining ligaments of the cheek, which, in addition to the SMAS itself, were still to be described. Since platysma is often less lax than neck skin, mobilising a skin/platysma flap also often did not satisfactorily deal with redundancy in the neck.

In response to failure of the traditional Skoog face-lift to correct malar fat descent, Hamra [33] developed the deep-plane face-lift. This elevated malar fat over zygomaticus major along with the Skoog (SMAS and skin) face-lift flap, and a skin/platysma flap inferiorly. A few years later Hamra further modified this technique, as the composite face-lift, to deal with poor upper midface rejuvenation [34]. In the latter technique, a composite flap including orbicularis oculi in addition to SMAS/platysma and malar fat was elevated. Hamra warns the reader that an extraordinary (author's own emphasis) amount of tension is necessary to reposition the composite flap of skin, SMAS/platysma and orbicularis and produce adequate rejuvenation.

SMAS techniques rely on the dissection, tightening and redraping of skin and SMAS/platysma as separate flaps. Many authors describe variations in skin incision, degree of flap mobilisation and flap tensioning/insetting. However, in general there is a continuous temporal, preauricular, postauricular and occipital incision, from which a subcutaneous flap is elevated to varying extents. Baker elevates skin up to a few centimetres lateral to the nasolabial fold, and from postauricularly to the anterior midline of neck. SMAS is elevated to the anterior border of parotid and tensioned posterosuperiorly, and skin redraped without tension, excising the excess.

Daniel Baker [35] questioned whether the high rate of transient facial nerve palsy in published series of deep-dissection face-lift was justified by any additional benefit. The development of his limited-incision face-lift with lateral SMASectomy was driven by a desire for less invasive face-lifting with less morbidity, and has proven a popular and reproducible technique incorporating some interceding anatomical principles – SMAS resuspension, different vectors for skin and SMAS, and retaining ligament release. After elevating subcutaneous flaps, Baker described excision of an oblique strip of SMAS from near the angle of the mandible to the malar prominence and reapproximation of the remaining SMAS. The excision is at the junction of fixed (lateral) and mobile (anterior) SMAS, so this manoeuvre exerts a posterosuperior vector of pull on the anterior midface. In thin faces the SMAS can instead be plicated to preserve volume, increasingly recognised as a feature of youthfulness. This procedure was originally developed for younger female patients with earlier ageing changes. More significant facial descent, as in the type III or IV patient of his classification (Table 1), may mandate an additional retroauricular incision to correct dog-ear formation.

Table 1. Classification of face-lift patients, modified from Baker (1997)

Type	Age	Characteristics
I – ideal candidate	40's	Slight cervical laxity with good elasticity Early jowls + Submental/submandibular fat + Microgenia
II – good candidate	Late 40s – late 50s	Moderate cervical laxity Moderate jowls Submental/submandibular fat + Microgenia
III – fair candidate	Late 50s – early 70s	Moderate cervical laxity Significant jowls Submental/submandibular fat + Microgenia Platysma bands with animation
IV – poor candidate	60s – 70s	Poor cervical elasticity Significant jowls Submental/submandibular fat + Microgenia Platysma bands with animation Skin folds below cricoid Deep cervical creases

There followed a period of popularity of limited incision surgery accompanied by SMAS manipulation with minimal dissection, usually in the form of plication or imbrication. The important difference between such techniques and those involving SMAS flap surgery is that the latter involves mobilisation of SMAS and surgical release of areas of ligamentous fixation, whereas the former does not.

Following the description of an S-shaped preauricular face-lift incision by Ansari [36], Saylan (1999) described his classic S-lift [37] - today perhaps credited more with being the predecessor to the 'minimal access cranial suspension' (MACS) lift [38] than in its own right. In the S-lift, a two centimetre sigmoid skin excision is marked and a subcutaneous plane immediately beneath hydrodissected by tumescent infiltration, after which subcutaneous tunnels are created with a liposuction cannula. There follows limited blunt subcutaneous dissection of the cheek, skin and SMAS excision, and so-called 'U' and 'O' purse-string sutures to suspend and plicate mobile SMAS and platysma to mastoid periosteum and zygomatic arch fascia using, as originally described, prolene suture. A later modification of the procedure - the S-Plus lift - extended the SMAS flap further into the midface, used two SMASectomies, purse-string imbrication of SMAS and malar cheek resuspension [39] (Figure 5).

Feeling that most patients with early midface ptosis requested a vertical facial elevation rather than the posterosuperior pull offered by conventional face-lifts, Tonnard and co-workers [38] modified the S-lift incision and points of fixation to describe the MACS lift. This is, strictly-speaking, a short scar procedure rather than a minimal access one (although 'MACS' is admittedly a punchier name than 'SSCS') which uses an inverted L preauricular and temporal incision and purse string sutures to achieve midface-lift. In keeping with the rejuvenation philosophies espoused by Little, Tonnard felt that the superior vector provides

facial and cervical rejuvenation whereas a lateral vector merely flattens the face. Other differences from the S-lift were tailoring, rather than predetermining, the extent of initial skin excision, and use of deep temporal fascia rather than zygomatic arch periosteum for fixation. U- and O-shaped purse-string sutures are used in a simple MACS-lift to tighten SMAS and lift jowls, and a third suture to the malar fat pad is used in an extended MACS-lift.

Figure 5. (LEFT) The S-plus lift: extent of subcutaneous flap undermining (grey) and SMAS excision (green). Mobile SMAS is elevated towards the fixed SMAS, lifting the midface and flattening the nasolabial folds (arrows). (RIGHT) The placement of purse-string U-, O- and M-sutures. The U- and O-sutures are imbrication sutures which close vertical and lateral SMASectomy. The M-suture is designed to lift the malar fat pad and cheek soft tissues vertically to produce midface fullness and lifting (after Hopping 2010).

Various surgeons are more or less aggressive in their facial dissections. Mendelson extends his beyond the zygomatic ligament, releases SMAS from zygomaticus major and sutures SMAS to zygomatic periosteum. Stuzin recommends extending the SMAS dissection over zygomaticus major, manoeuvre that relies on innervation of most facial muscles coming from their deep surface. Debate rages as to the optimal balance between surgical aggressiveness, safety and relative efficacy.

IS ANY FACE-LIFT TECHNIQUE SUPERIOR?

With a number of differing philosophies to facial rejuvenation surgery, from each of which has arisen various improvements and variations, naturally the question of whether any one represents a marked improvement over the others crops up.

The main proponents of each technique have all reported satisfactory results in their respective series. Hamra and Lennon published a large favourable experience of over 500

Skoog face-lifts (Hamra and Lennon, 1984), before moving on to similar series of deep plane and composite face-lift procedures. Positive results were reported in 403 patients undergoing the deep-plane technique, complications including one percent major (requiring evacuation) haematoma and one percent transient lip paresis. Kamer's [40] prospective questionnaire evaluation of 100 patients six months after deep-plane face-lift demonstrated that 97% of patients were pleased with their outcome. The haematoma rate was 2.8% and there were few other identified complications.

In his experience of 167 composite face-lifts, Hamra [34] encountered one cervical haematoma requiring evacuation and no facial nerve injuries. He warned that malar tenderness and swelling might persist for several months after the procedure. The actual aesthetic outcome was not formally assessed, but Hamra criticised previous SMAS face-lifts for producing an 'operated look' resulting from good neck rejuvenation despite a deep nasolabial crease, and felt that the composite face-lift produced a more harmonious result.

Baker [41] reported his series of lateral SMASectomy in over 1500 patients, finding it most beneficial in early ageing (types I and II of his classification, Table 1), but also applicable to types III and IV when modified to improve jowl elevation and a traditional incision used to deal with a retroauricular dog ear. However, he felt the technique was less well suited to male patients owing to thicker skin and muscle of the neck. The commonest complication was the need for neck revision (four percent), although Baker noted a similar experience with traditional face-lift and the observation appears just as relevant today [42]. He additionally reported three percent temporal hairline scar revisions, two percent earlobe scar revisions, two percent secondary mini-lift after one year, 1.5% hematoma and 0.1% facial nerve weakness. Massiha [43] also noted high patient satisfaction in his series of "several hundred" short-scar lateral SMASectomies similar to Baker's. Outcomes were not quantified, but there were no reported instances of nerve injury or skin necrosis, and complications were described as rare and minimal.

In his description of the technique, Saylan (2002) gave an account of his experience of S-lift in 250 patients. Complications included transient facial nerve palsy (1.2%), minor haematoma (0.8%), and self-limiting pretragal tension (17.6%). A majority of patients (76%) experienced dimpling beneath the ear lobe due to traction on the platysma, which could be improved by liposuction with a sharp cannula (presumably to produce soft tissue tunnelling and distribute or attenuate the tension). Saylan felt the procedure was best suited to younger patients with good skin quality and early ageing changes (Baker type 1 patients). Again outcomes were not formally quantified.

Tonnard and co-workers [44] reported on over 450 MACS-lifts on patients with a mean age of 57. Dog-ears were not chased and all settled by two months. Short recovery was cited as an advantage of this technique, the authors reporting most patients being able to return to normal activity after one week, with none requiring camouflage make-up beyond two weeks. Two per cent of patients required evacuation of haematoma. Adequate facial suspension was maintained by eighteen months, which was the longest follow-up in the series, although five percent required revision surgery to correct the neck.

In a review of 54 patients undergoing short scar volumetric face-lift [45], three independent surgeons graded preoperative and three month postoperative photographs of a random sample of 25 of those patients. The authors reported no significant complications, aesthetic outcomes were generally rated as 'Good' (with none rated 'Poor') and improvements in malar eminence soft tissue volume, the nasolabial fold, jowls and the

cervicomenal angle. The authors concluded that short scar volumetric malar imbrication face-lift was a straightforward, safe and effective procedure for improving early ageing.

Various other studies express their opinions on the effectiveness of individual techniques. For instance: one case series review of 539 patients concluded that less invasive procedures resulted in less morbidity, durable results and high patient satisfaction [46]; another retrospective review of 83 patients concluded that a short incision and limited subcutaneous dissection face-lift resulted in high levels of satisfaction with a low complication rate⁴⁷; a review of 135 patients undergoing minimally invasive endolaser face-lift combined with suture suspension, cutaneous laser therapy and fat grafting concluded that results were satisfactory [48]. However, interpretation of all these uncontrolled studies is difficult. For example, close analysis of the latter study revealed an 18.5% complication rate, and the study was diminished by lack of quantification, indication of length of follow up, no control group and the difficulty in assessing the relative contributions of the various adjunctive therapies.

Despite these extensive series representing a significant body of experience of prominent surgeons, none are controlled comparative studies. The differences in methodologies, including patient populations, operating surgeons, anaesthesia, and outcome intervals and assessments, make comparison of the different techniques almost impossible. Several investigators have therefore attempted to make direct comparisons between types of facial rejuvenation procedure in order to address whether one is better than any other. In assessing the evidence presented, we have adhered to the Level of Evidence classifications adopted by the American Society of Plastic Surgeons (Appendix)

Table 2. Summary of studies directly comparing midface-lift procedures.
See text for explanation

Author	Procedures	Study size	Summary	Evidence Level
Ivy et al. (1996)	lateral SMASectomy/ conventional SMAS vs. extended SMAS/ composite face-lift	21	Procedures equivalent after 24 hours.	II
Kamer & Frankel (1998)	SMAS vs. deep plane face-lift	634	Fewer 'tucks' following deep plane.	III
Litner & Adamson (2006)	SMAS plication vs. imbrication vs. deep plane	32	Best intraoperative lift with deep plane.	II
Prado et al. (2006)	MACS vs. lateral SMASectomy	82	No difference in cosmetic outcome or satisfaction.	III
Antell and Orseck (2007)	Combinations of skin only vs. conventional SMAS vs. lateral SMASectomy vs. SMAS plication	16 (8 twins)	No discernible difference.	III

The relevant studies are summarised in Table 2. Litner and Adamson (2006) carried out a prospective study comparing limited versus extended face-lift techniques. Each hemiface of 32 patients underwent a progressively more extensive face-lift procedure (SMAS plication, then imbrication, then deep plane face-lift) and data was collected intraoperatively (Evidence Level II). The authors concluded that a superior intraoperative lift was obtained using the deep plane technique, but the study design did not permit any comparison of longevity. This is important since other work suggests that such early differences may not correlate with longer-term outcome.

For instance, Ivy and colleagues (1996) carried out a split-hemiface prospective randomised controlled trial comparing more conservative (either lateral SMASectomy or conventional SMAS lift) with more extensive (extended SMAS or composite face-lift) surgery (Evidence Level II). In this analysis of 21 patients, assessments were made intraoperatively and at 24 hours, and were reviewed by six surgeons using postoperative photographs at six months and one year. Greatest intraoperative changes determined by SMAS overlap, nasolabial fold effacement and midface movement were achieved with the more extensive procedures, but this difference was lost at 24 hours and subsequent time points. The possibility remained that more extensive surgery produced a result of similar magnitude but greater longevity compared with conservative surgery, but the maximum follow up of one year was unable to demonstrate this.

Prado and co-workers (2006) retrospectively compared two minimal incision procedures (MACS lift and SMASectomy) in 82 patients (Evidence Level III). Patients and two independent plastic surgeons assessed postoperative photographs at one month and two years. The MACS procedure was quicker to perform but was associated with more postoperative pain. However, the cosmetic outcome and patient and surgeon satisfaction were similar for either procedure. Overall there was no clear benefit to one procedure over the other.

Antell and Orseck (2007) published an interesting series of eight pairs of twins who had undergone various face-lift procedures: skin only; conventional SMAS; Baker-type SMASectomy; and SMAS plication. Follow up photographs taken between thirteen and sixty months postoperatively were evaluated by four blinded Plastic Surgeons. Again, the authors concluded that no one technique was superior to any other. Although the occurrence of eight pairs of monozygotic twins who had all had face-lifts in a single series was noteworthy, the chance nature of these comparisons was evident. For instance, four siblings (two twin pairs) underwent the same procedure and could justifiably have been excluded from the series. There was no standard follow-up interval across twin pairs, and even within twin pairs it is unclear whether assessment always took place at the same postoperative follow-up interval. These factors, combined with the (understandably) small series, make data interpretation problematic.

Due to inherent difficulties in making aesthetic judgements of the outcomes of different techniques, Kamer & Frankel (1998) attempted to assess the efficacy of SMAS versus deep plane face-lift techniques objectively by retrospectively evaluating the need for revision procedures within eighteen months ('tuck rate') in 634 patients. They found that such procedures were performed significantly less frequently following deep-plane face-lift (3.3% vs. 11.4%). However, the indications listed for determining the need for a tuck (inelastic skin, deep nasolabial folds, jowl, cheek or malar redundancy, and patient dissatisfaction) were themselves subjective, so the objectivity of the rate of revision surgery can be questioned. Additionally, since SMAS procedures were carried out early in the series whereas deep plane face-lifts were performed in the latter half, the declining revision rate could be commensurate with increasing experience.

In conclusion, there remains no clear evidence of greater effectiveness of any particular technique over any other, although no study has really effectively addressed the question. It is a difficult one to address objectively due to differences in preoperative patient desires, variations in anatomy, variations between surgeons and intrinsic subjectivity of aesthetic outcome assessment. Nonetheless, there appears to be some convergence in techniques towards the common themes of decreasing reliance on skin tension through SMAS

manipulation, increasing use of vertical vectors of resuspension rather than purely lateral ones, and the recognition of the importance of volume preservation in many patients.

Adjunctive Measures, Complications & Their Avoidance

1. Preinfiltration

Following the successful use of tumescent anaesthesia to reduce blood loss in liposuction, Brody [49] attempted a similar strategy for face-lift surgery after a run of haematomas. He reported “impressive results” with greatly reduced intraoperative bleeding, easier tissue dissection, reduced operative time and no further haematomas. This led to the widespread adoption of preinfiltration prior to face-lift surgery, although formal evidence did not yet exist.

This was addressed ten years later in a study by Jones & Grover [50], who studied the effect of tumescent infiltration on postoperative complications. Using a retrospective comparative study design in a cohort of 678 patients (Evidence Level III), the first 449 patients, who did not receive tumescence, was compared with the next 229 who did. Tumescent solutions consisted of local anaesthetic, adrenaline, hyaluronidase and corticosteroid, and procedures were performed under hypotensive general anaesthesia by an experienced anaesthetist. The investigators found that use of tumescent anaesthesia reduced postoperative swelling, oozing, skin necrosis, alopecia, hypertrophic scarring and scar stretch, and noted that tumescence made dissection of skin flaps easier, particularly in the neck. Interestingly, tumescent infiltration did not significantly alter the rates of major or minor haematoma – indeed there was a non-significant increase in haematoma rate in the group who received tumescence.

A mechanism by which tumescent preinfiltration may reduce the complications noted in this study is not immediately obvious. The authors speculated that the key mechanism might have been reduced skin flap tension, resulting either from intraoperative tissue expansion (a mechanical effect of the infiltrate) or from reduced postoperative swelling (a pharmacological effect of locally administered corticosteroid) [50]. An alternative mechanism could simply have been facilitated dissection of an optimal skin flap plane by preoperative hydrodissection.

Preinfiltration has become an established routine for most face-lift surgeons. The composition and relative concentrations of the tumescent solution is far less ubiquitous, however, and there is little strong evidence to guide this. Two early reports of preoperative infiltration for face-lifting used only dilute lidocaine and adrenaline [49,51]. Other surgeons add varying amounts of triamcinolone and hyaluronidase [52]. In Brody’s opinion, the composition of infiltrate is not important, it being simply necessary to infiltrate a substantial volume; he wondered whether saline alone might have a similar effect.

One study looking at the composition of infiltration [50] compared tumescence with and without adrenaline in a case-control study of 910 patients, finding a significant reduction in both major (from 4.8% to no events) and minor (from 2.6% to 0.4%) haematomas when adrenaline was omitted. Other measures – dressings, drains, fibrin glue and tumescence – did not affect haematoma occurrence. The authors concluded that adrenaline should be omitted from preinfiltration solutions prior to face-lift. Adrenaline use could increase the rate of postoperative haematoma formation by temporary vasoconstriction (its desired intraoperative

effect) making it more difficult to identify bleeding vessels and perform effective surgical haemostasis. Knize {Knize:2004ch} felt that the increased speed of surgery associated with adrenaline-containing tumescence increased the risk of reactive vasodilatation.

To our knowledge, little other evidence on the composition of tumescent infiltration prior to face-lifting exists, although anecdotally most practitioners agree that tumescent infiltration itself is a useful, or indeed mandatory, adjunct.

2. Fibrin Tissue Adhesives

There is an unusual amount of good evidence assessing the use of fibrin glue in face-lifting (summarised in Chapter 30, Table 1.), possibly due to acceptability to patients and surgeons of split-hemiface double-blind randomised controlled trials with or without tissue sealants, for which there may be equipoise regarding efficacy and only minor concerns of adverse events. The main theoretical advantages are a haemostatic effect with reduced haematoma rates, and reduced incidence of seroma or prolonged drainage by closing dead space from dissected tissue planes. Potential disadvantages include cost, the risk of transmissible disease (with the use of donor rather than autologous fibrin), allergy and, importantly, unproven efficacy.

Table 3. Studies examining the influence of fibrin tissue adhesive on the postoperative course of face-lift surgery. (* = statistically insignificant or no statistical scrutiny; X = not assessed)

	n	Effect of fibrin on

Marchac and co-workers [53] examined the effect of fibrin tissue adhesive in 65 patients undergoing face-lift with a hybrid uncontrolled and split-hemiface study. For the ten patients in the split-hemiface part of the study there was no difference between the two sides in five cases and the glued side was judged superior in the remainder. Overall Marchac felt that the tissue adhesive had a beneficial effect.

Oliver and co-workers' experience was broadly similar to that of Marchac [54]. Their prospective double-blind randomised controlled trial of twenty patients undergoing face-lift with bilateral drainage and fibrin glue to one side only (Evidence Level II) demonstrated significantly reduced drain output at 24 hours (ten millilitres versus thirty millilitres) on the fibrin side. The researchers felt that this difference could be enough to replace the use of drains.

One objection to donor derived blood products such as fibrin – potential disease transmission - is obviated by use of autologous products. Man and colleagues [55] enrolled twenty patients for their study into the effect of autologous fibrin, derived from platelet-poor plasma, on postoperative outcome following face-lift and/or neck lift, breast augmentation or mastopexy. They observed that the fibrin rapidly stopped intraoperative capillary bleeding and felt that it reduced operating times, reduced postoperative swelling, shortened recovery and avoided drain use. However, none of the results were quantified and there was no control group in this study, making objective interpretation of the data difficult. The same year, Powell [56] investigated the efficacy of autologous platelet gel in a prospective randomised controlled trial of eight patients undergoing deep plane face-lift, comparing treated and untreated hemifaces by means of blinded postoperative photographs (Evidence Level II). Platelet gel was found to reduce bruising and swelling.

Fezza [57] carried out a prospective clinical trial comparing the use of drains alone after face-lift in 24 patients with fibrin glue and no drains in the next 24 (Evidence Level II) - essentially, a comparison of fibrin glue versus drainage. Use of fibrin was associated with less bruising and swelling as determined by nurse observers from pre- and postoperative photographs, a thirteen minute shorter operative time, subjectively 'faster healing' and fewer complications (zero versus 8.3% haematoma requiring evacuation). The latter was not significant however, corresponding to zero versus two actual haematoma events in the fibrin and non-fibrin groups respectively. Although common, sequential analysis can produce bias resulting from an advancing learning curve, in that late results tend to be superior to earlier ones. This effect is most relevant when using outcome measures such as operative time, which is highly dependent on experience and less apparent for very experienced practitioners whose technical improvement may have levelled. The observation of reduced operative time in the fibrin study group is difficult to explain - it cannot be accounted for by the time taken to insert drains, and haemostasis should be similarly rigorous whether fibrin is used or not. A potential explanation could be an active learning curve within this series.

In their series of face-lift patients, Grover & Jones [58] sprayed fibrin glue beneath the skin flaps in 412 patients, and in 266 patients, no glue was used. There was an overall haematoma rate of 4.1% and the use of fibrin glue did not have any effect on this. This was in keeping with their earlier multivariate analysis of risk factors for haematoma following facelift in 1078 patients [59], which found that Tisseal had no beneficial effect (haematoma rates of 4.4% and 4.0% with and without use of Tisseal respectively).

The prospective unblinded split hemiface randomised controlled trial of Marchac and Greensmith is widely cited [60]. The authors compared the use of fibrin glue with none at the

end of face-lift surgery in thirty patients (Evidence Level II). Surgical drains were also used and drain output at 24 hours taken as one outcome measure. Whilst there was a statistically significant reduction in drain output with the use of fibrin glue (26ml vs. 34ml), the authors felt the magnitude of that difference was clinically irrelevant, in contrast to the earlier study of Oliver [54]. Subjective assessment of oedema and ecchymosis at days one and eight also revealed no striking difference between hemifaces, and the authors disagreed with Fezza's determination that the use of fibrin glue reduced operative time [57]. In contrast, they argued that its use added a further operative step, and since meticulous haemostasis was not obviated by use of fibrin glue the net effect was to increase the length of the whole procedure. One haematoma in the study (on an unglued side) did not permit statistically meaningful comment. Overall, the authors believed that drains were more important than fibrin glue, and since adopting the use of the former no longer required the latter.

Kamer & Nguyen carried out a case-control study prospectively evaluating the outcomes of deep plane face-lift using fibrin glue in 100 patients, compared with the retrospective outcomes of 100 patients without use of fibrin (Evidence Level III) [61]. Whilst the authors felt the use of fibrin conferred a number of benefits, the only ones achieving statistical significance were a reduction in prolonged induration, oedema and ecchymosis, from 22% to no instances. Reductions in the instances of expanding haematoma (from three to one percent) and seroma (from seven to one percent) were not statistically significant, but the authors nonetheless believed them to be 'clinically significant'.

Zoumalan and Rizk [62] conducted a retrospective case-control study of the impact of fibrin glue and no drains in 605 patients undergoing either deep-plane or (in a minority) lateral SMASectomy face-lifts. In their series, no patient experienced major haematoma but the minor haematoma rate was significantly reduced by the use of fibrin (3.4% vs. 0.4%). Most minor haematomas occurred in men, consistent with their greater risk noted elsewhere [59], and a significant protective effect of fibrin was only apparent in the male subgroup. The authors noted that almost a third of haematomas were associated with postoperative vomiting and recommended prevention and prompt treatment of nausea.

In their small split-hemiface randomised controlled trial comparing fibrin sealant versus none in nine patients, Lee and colleagues [63] found tissue sealant significantly reduced bruising and swelling at days three and seven (Evidence Level II), as judged by five blinded independent observers. Whilst there appeared to be a beneficial effect of the tissue sealant on the prevention of small haematomas (22% vs. 0% in the untreated and treated groups respectively), the study lacked sufficient power to show statistical significance. There were no major haematomas in the study.

Por and colleagues (2009) [64] performed a small meta-analysis into the use of tissue sealants in face-lift (Evidence Level 1). This was based on the pooled data of the randomised controlled trials of Marchac⁶⁰, Oliver⁵⁴ and Powell⁵⁶. Tissue sealants produced a non-significant trend towards reduced drainage. There was no effect on ecchymosis or oedema.

In their prospective split hemiface randomised controlled trial of 120 patients, Mustoe and co-workers⁶⁵ found fibrin tissue sealant significantly reduced the rate of seroma/haematoma and the volume of drain output formation following face-lift.

An overall view of the literature therefore suggests some benefit of fibrin glue in terms of bruising, swelling and possibly early drain output. However, benefit in terms of haematoma risk reduction is demonstrated inconsistently, and if there is such an effect at best it is likely to be small. In view of this, the potential (admittedly small) risk of disease transmission, and

the additional cost of using the product, there does not appear to be overwhelming support for the use of fibrin glue.

3. Drains

Opinion differs regarding the use of drains following face-lift surgery. Huang and colleagues [66] investigated use of suction drains in 46 patients, comparing sixteen in whom a drain was placed on the left side, fourteen in whom it was placed on the right and sixteen in whom no drain was used. All drains were removed after 24 hours irrespective of drain output. The single haematoma that occurred in the study was on a drained side following its removal, although the study size is too small to draw any meaningful inference. Huang felt that each hemiface in unilaterally drained sides was identical, and that these patients were postoperatively indistinguishable from those who received no drains, concluding that drains were probably unnecessary.

In contrast, Perkins' group [67] felt that drainage had some benefits following face-lift. They retrospectively reviewed 222 face-lifts performed by one surgeon using the same technique, half with and half without drains, measuring the occurrence of haematoma or seroma within 24 hours. Their series contained several minor haematomas - needing aspiration only - and seromas. Drainage appeared to reduce seroma frequency significantly (15% vs. 37%) although it had no significant affect on haematoma rate (7% vs. 8%). As previously discussed, Marchac [60] decided to discontinue the use of fibrin tissue adhesive after introducing drains into his practice, feeling that they achieved similar functions - reducing the dead space of elevated flaps - but that drains were more important.

Aiming to address conflicting opinions regarding drain usage, Jones and colleagues [68] carried out a split-hemiface prospective randomised controlled trial of the use of Medinorm low suction Bellows drains following face-lift surgery, in which one half of the face was drained and the other acted as control, in fifty patients (Evidence Level II). Patient and clinician assessment at one day and approximately one week postoperatively found no effect on postoperative oedema or haematoma rate with the use of drains. There was, however, a reduction in postoperative bruising associated with their use, and consequently a speedier return to normal activities.

The use of drains following face-lift surgery remains a matter of individual surgeon preference, opponents citing little benefit, and proponents citing some benefit with little downside.

4. Haematoma

Haematoma is the commonest complication of face-lift, the literature quoting rates of two to nine percent (Table 4). Large haematomas can compromise skin flap perfusion and, unless treated expediently, result in skin necrosis. Small haematomas may have little immediate impact, only being detected after initial swelling has subsided, but can lead to contour irregularities, altered skin pigmentation, infection, persistent postoperative oedema and prolonged convalescence.

Kamer & Song [69] retrospectively investigated 451 deep plane face-lifts, establishing a rate of major and minor haematoma of 2.2% and 6.65% respectively. Haematomas occurred much more frequently in men, in keeping with other studies (five versus two percent for major and twelve versus six percent for minor) and all haematomas occurred in the

subcutaneous dissection plane used in the neck, rather than the deep plane of dissection used in the face. The authors commented that the latter plane is relatively avascular and, in their view, less likely to produce haematoma than raising a subcutaneous flap.

**Table 4. Reported incidence of haematoma following face-lift.
(Adapted from Grover & Jones 2001)**

Study	n=	% haematoma
Rees et al. (1973)	806	3.3
Straith et al. (1977)	500	2.6
Leist et al. (1977)	324	3.4
Perkins et al. (1997)	222	7.5
Kamer (1998)	100	2.8
Rees et al. (1994)	1236	1.9
Marchac & Sandor (1994)	200	2-9
Jones (1995)	137	3.6
Grover & Jones (2001)	1078	4.2
Durnig & Jungwirth (2006)	126	5.6

Grover and colleagues (2001) investigated preoperative and intraoperative risk factors for haematoma following face-lift in a large case-control study of 1078 patients (Evidence Level III) [59]. Since risk factors commonly coexisted, multivariate analysis was used to identify independent risk factors and their individual relative risks.

The findings were surprising (Table 5). Against an overall haematoma rate of 4.2%, the risk factor most strongly related to haematoma formation was concurrent anterior platysmaplasty, which had not previously been identified. Next were uncontrolled systolic hypertension, male gender, aspirin or non-steroidal use, and smoking. The type of face-lift, whether it was primary or secondary, patient age, use of fibrin sealant, and cardiovascular or pulmonary comorbidity, did not affect haematoma rate. Relative risk for each significant risk factor was calculated (Table 6), aiming to guide preoperative patient counselling. Risk factors are cumulative - thus a male smoker taking aspirin would have a 7.2 times increased haematoma risk.

On the basis of this study, preexisting hypertension should be treated, the patient should be counselled on smoking cessation if relevant, and if medically permissible aspirin or NSAIDs should be discontinued. Whilst anteriorly platysmaplasty is still commonly carried out, the surgeon should be aware of the increased risk of haematoma and be particularly diligent with regards haemostasis.

The same study suggested that the increased haematoma risk from aspirin/NSAIDs more or less normalised within two weeks of their discontinuation. This conclusion was formed from comparison of the NSAID/aspirin users in the haematoma (14/45) and non-haematoma (31/1033) groups: nine of the fourteen NSAID/aspirin users in the haematoma group had discontinued the medication within two weeks of surgery, whereas 26 of the 33 NSAID/aspirin users in the non-haematoma group has discontinued more than two weeks before their face-lift.

Table 5. Significant and non-significant factors for the development of postoperative haematoma following face-lift (data from Grover et al. 2001)

Significant factors (Relative risk)	Non-significant factors
Anterior platysmaplasty (4.3)	Type of facelift
Preoperative SBP>150mmHg (3.6)	Primary or secondary procedure
Male gender (2.8)	Cardiovascular/pulmonary comorbidity
Use of aspirin/NSAIDs (2.3)	Use of fibrin tissue adhesive
Smoking (2.1)	Operating surgeon
	Patient age

5. Smoking

Krueger & Rohrich [70] reviewed the effects of cigarette smoking on plastic surgery procedures. The many inhaled products of tobacco smoke influence wound healing via several pathways, including direct microvascular injury, inhibition of the function and proliferation of inflammatory cells, stimulation of hormones that retard epithelialisation, cutaneous vasoconstriction and competitive binding of toxins to haemoglobin. In addition, increases in platelet adhesiveness, plasma fibrinogen concentration and blood viscosity combined with altered red blood cell rheology predispose to occlusive microvascular thrombosis, which can have a more chronic impact on the response to injury. Delayed healing, wound dehiscence, postoperative infection and poor scarring are therefore all more likely in a patient who smokes.

Rees and colleagues reported their retrospective observation following 1186 face-lifts that smokers were more than twelve times more likely to suffer skin slough postoperatively [71]. Riefkohl and colleagues [72] subsequently carried out a prospective comparative study into the effect of smoking on occlusive vascular disease and skin slough after face-lift, by comparing histological assessment of excised preauricular skin and rates of skin slough in active smokers, ex-smokers and non-smokers (Evidence Level 2). In total 83 patients were assessed, and there were nine cases of skin slough, with a frequency of five percent in non-smokers and twenty percent in active smokers. Whilst striking, this difference was not statistically significant. However, occlusive vascular disease was increasingly noted with advancing age and smoking, and there was a significant association between severe occlusive vascular disease and skin slough. Amongst smokers, there was also a significant association between skin slough and postoperative failure to abstain from smoking.

We are only aware of one study examining the effects of smoking on the outcome of face-lift surgery that failed to find an adverse effect. Webster and co-workers [73] reported no skin sloughs in their population of 407 patients undergoing skin slough, of whom 32.4% were active cigarette smokers. However, this group raised facial flaps more conservatively specifically with a view to designing a procedure that was relatively safe in smokers.

Smoking is implicated in the study of Grover and co-workers [59] investigating haematoma after face-lifts, who found it to be a risk factor. 6.1% of patients with a positive smoking history sustained a haematoma compared with 3.7% of non-smokers. Although smoking has an overall prothrombotic effect, such a relationship could arise from, for example, impaired mucous clearance and increased coughing in the convalescent period, dislodging thrombin clots.

The optimal period of smoking cessation, or the degree of smoking reduction required to normalise risk levels, are not known. Consensus opinion cannot be derived from the literature, with recommendations ranging from cessation one day to four weeks preoperatively and five days to four weeks postoperatively. Haematological parameters - blood and plasma viscosities, haematocrit, blood cell filterability, plasma fibrinogen levels, and total white blood cell count - normalise over a period of around eight weeks [74].

6. *Hilotherapy*

Cooling devices designed for use after facial injuries are commercially available and used by some practitioners following face-lift surgery, although little evidence exists for that indication. Research has demonstrated that cooling with gel packs and ice bags reduces pain, bruising and eyelid swelling after craniotomy [75], and that a Hilotherm cooling face mask reduces pain and swelling compared with cold compresses after mandibular fracture fixation [76] or dental extraction [77]. However, a literature review found study data regarding the benefits of cooling after oral surgery to be inconclusive [78].

Jones and coworkers [79] randomised fifty patients to either standard dressings or hilotherapy following face-lift (to assess bruising, swelling and haematoma) and a further fifteen to hilotherapy cooling on one side of the face only (to allow more accurate comparison of an effect on postoperative pain). Surprisingly the researchers found significantly increased postoperative swelling in patients who received cold therapy, with no statistically significant effect on bruising, haematoma or postoperative pain. Whilst evidence is currently exceptionally sparse, there exists none at present that would encourage the use of hilotherapy after face-lift.

7. *Thromboprophylaxis*

Low molecular weight heparin is commonly used in the postoperative period of many surgical procedures to reduce the risk of thromboembolic disease, based on effectiveness shown in multiple studies addressing general, orthopaedic and urological surgery [80]. In the United Kingdom, the regimen of mechanical and chemical thromboprophylaxis is determined by patient risk stratification [81]. The majority of patients undergoing face-lift would be considered moderate risk - aged over forty, undergoing surgery longer than thirty minutes duration, without additional risk factors. Recommendations for such patients are to receive 2000-3000IU of heparin per day until mobile [82].

Despite this, Durnig and Jungwirth argue against LMWH thromboprophylaxis following face-lift⁸³. In their retrospective comparative study of 126 patients (Evidence Level III), 89 received only perioperative compression stockings, early mobilisation and analgesation and the remainder also received LMWH. There were no instances of symptomatic thrombosis or pulmonary embolism. However, sixteen percent of patients from the LMWH group experienced postoperative bleeding compared with one percent of patients not receiving LMWH. Based on this, the authors felt that patients should not routinely receive LMWH following face-lift. They reserved chemoprophylaxis for patients with known risk factors such as prothrombotic conditions, relevant past history and use of the contraceptive pill.

Durnig and Jungwirth felt that their use of analgesation rather than general anaesthesia was relevant to their low rate of postoperative thrombosis, based on a survey by Reinisch and colleagues [84] in which 0.35% of their sample of 9937 face-lift patients developed deep vein

thrombosis, but 84% of thromboembolic events occurred in association with general anaesthesia. Thus their conclusions regarding the need for heparin chemoprophylaxis may not apply to patients undergoing face-lifting under general anaesthesia.

8. Hair Loss

Hair loss can result from face-lift surgery either from excision of hair-bearing skin (causing posterior or superior retraction of the hairline, particularly around the sideburn or temporal area), as a result of scar alopecia from incisions placed within hair-bearing scalp, or through damage to hair follicles on the underside of elevated skin flaps (e.g. resulting from diathermy). The former is a consequence of incision design and vector of skin redraping, and as such should be explicitly controllable by the surgeon.

To minimise scar alopecia, there have been differing opinions as to whether to bevel scalp incisions so they are parallel to hair follicles (minimising the number of follicles injured) or perpendicular to them (leaving the possibility of hairs growing through and disguising the scar). Camirand states he was inspired to attempt the latter by the success he had observed of follicular grafts in treating alopecia, conceptualising the bevelled scar containing deep hair follicles essentially as follicular flaps which could permit hair growth into the overlying scar [85].

Camirand and co-workers therefore compared scars resulting from these alternative incision designs as part of a double-blind comparison in which eighteen patients acted as their own controls, and four observers were asked to state which side had the more aesthetic scar [85]. There was a significant preference for the side with the perpendicular bevelled scar and the author was able to demonstrate hair growth through the scars on the perpendicular side as intended. Moreover, Camirand points out it is actually easier to perform a perpendicular bevelled scar rather than a parallel one matching the constantly changing direction of hair follicle growth.

HOW LONG DOES A FACE-LIFT LAST?

It seems appropriate to end an overview of face-lift surgery with consideration of how long the procedure will last for - a question commonly asked by patients considering whether to embark on the process, and one which has recently been addressed. Jones & Lo [42] carried out a retrospective assessment of the outcome of face-lift, performed by SMASectomy/SMAS plication and lateral platysmaplasty or using the volumetric approach of Little [86], on standardised photographs taken prospectively over the previous ten years. Software was used to measure the movement of key facial points in the early and late (5.5 years) postoperative period.

At the late time point the researchers found good maintenance of correction of the jawl, nasolabial fold and marionette regions, but significant relapse of the neck. Global subjective assessment determined that three quarters of patients looked younger after 5.5 years than at the time of presentation, and adverse stigmata of face-lift did not occur. Thus the post-facelifted patient ages differentially, losing neck correction sooner than elsewhere. Overall, the authors concluded, patients could be reassured of the longevity of their aesthetic gains.

CONCLUSION

The face is of unique importance both to self image and the image projected to others. Advances in our understanding of the interaction between anatomy and ageing have fuelled changes in face-lift techniques that have been, at times, stepwise and at other time more significant sea changes. Despite the existence of enthusiasts for one technique or another, and a fair body of research seeking a technique that is better than the rest, there is at present no clear winner. A skilled surgeon carrying out a technique with which they are experienced in an appropriately selected patient is likely to achieve a satisfactory result, which an overall view of the literature suggests would most likely be indistinguishable from a different but equally applicable procedure carried out by a similarly experienced surgeon. The importance of patient selection cannot be overemphasised, and published series cannot take into account those patients turned away as physically or psychologically unsuitable for surgery.

Chapter 33

RHINOPLASTY

Samuel Hahn*, MD and Oren Friedman, MD

Department of Otolaryngology - Head and Neck Surgery,
University of Pennsylvania, Philadelphia, PA, US

KEY POINTS

- Understanding anatomic distribution of the soft tissue envelope and osseocartilaginous structure, specifically the nasal valves, is critical to successful surgical planning in rhinoplasty.
- Careful assessment of nasal function prior to rhinoplasty is important, however subjective and objective measures may not correlate; a graded approach should be used to help guide management
- Management of the upper third of the nasal vault requires judicious use of osteotomies for control of the nasal bones. Both continuous and perforating methods of osteotomies provide excellent control and outcomes but studies show that perforating osteotomies may result in less postoperative edema.
- Spreader grafts are widely used in cosmetic rhinoplasty; despite lack of well-designed studies, there appears to be ample clinical studies suggesting that spreader grafts are beneficial in improving nasal aesthetics and function.
- Literature supports the use of irradiated homologous costal cartilage (IHCC) as a viable option for grafts in rhinoplasty. Postoperative complication rates using IHCC were comparable to autogenous cartilage grafts
- A graded approach in tip refinement that focuses on tip stabilization and maintaining and/or augmenting supportive structures of the tip is necessary to produce successful long lasting results
- Perioperative dose of steroid may help decrease postoperative periorbital edema and ecchymosis

INTRODUCTION

Rhinoplasty can be one of the most technically challenging cosmetic operations. Successful rhinoplasty requires a thorough understanding of both structural and aesthetic components of the nose as well as the face. The surgeon must carefully evaluate not only the patient's nasal anatomy and function but also understand their motivation and desired outcome of surgery. This complete knowledge will help the surgeon balance the form and function of the nose necessary for successful long-term results.

While the basic components of rhinoplasty have not significantly changed over the years, there have been many differing opinions of surgical approaches and contouring techniques. Much of the evidence supporting rhinoplasty techniques has been based on retrospective case series with validated outcome measures being regularly implemented only in the recent past [1]. Due to the varying degrees of subjective influence on the rhinoplasty outcomes, i.e., patient satisfaction in appearance and functionality of the nose, it is important to understand the available techniques and expected outcomes based on patient anatomy and physiology. Having an evidence-based approach to rhinoplasty will help the rhinoplasty surgeon achieve optimal success.

NASAL ANATOMY AND FUNCTION

Thorough understanding of nasal anatomy is essential for successful nasal surgery. The human nose is a complex three-dimensional structure comprised of the external skin and soft tissue envelope, an osseo-cartilaginous framework and an internal mucosal lining. It is important to understand the relationships between the anatomic components that give each patient a distinct appearance. Congenital and acquired nasal deformities present surgical challenges that require application of demanding technical manoeuvres to the anatomical components to enhance nasal appearance and function safely and effectively [2-4].

Externally, the nose is covered by the skin and soft tissue envelope. This is composed, in increasing depth, of epidermis, dermis, subcutaneous fat, fibromuscular tissue, the deep fatty vascular layer, loose areolar tissue and periosteum/perichondrium. The nasal musculature lies within the fibromuscular layer of the nose within the superficial musculoaponeurotic system (SMAS). An appreciation of the skin is essential in preoperative surgical assessment and intraoperative surgical execution as skin quality plays a significant factor in the final aesthetic result and the surgical technique chosen for rhinoplasty will depend on individual skin quality, thickness and texture for each patient [3-5]. For example, providing definition of the nasal tip often requires significantly greater tip support in thick-skinned individuals compared with thin-skinned ones; whereas use of a camouflaging onlay soft tissue graft is required more often in thin-skinned patients.

The structural framework of the nose is composed of paired bony and cartilaginous elements. Successful surgical outcomes depend on proper maintenance and restoration of this framework. The nose can be divided into upper, middle and lower vaults (Figure 1). These vaults provide the structural support and three-dimensional height and projection of the nose. The upper (bony) vault is comprised of the paired nasal bones and the paired ascending processes of the maxilla. The middle (cartilaginous) vault is composed of the upper lateral cartilages and the cartilaginous dorsal septum.

Figure 1. Thirds of the nose and the keystone area. The upper third is comprised of the bony structures whereas middle and lower thirds are cartilaginous structures. The “keystone” area (dotted box) is the site of convergence of the nasal bones, the perpendicular plate of the ethmoid bone, the upper lateral cartilages and the cartilaginous septum.

The point of transition from the bony upper vault to the cartilaginous middle vault is the rhinion. It is here the upper lateral cartilage and perichondrium inserts on the undersurface of the nasal bone. This region is also referred to as the keystone area and represents the site of convergence of the caudal margin of the nasal bones, the perpendicular plate of the ethmoid bone, the superior margin of the upper lateral cartilages and the cartilaginous septum (Figure 1). It is important to understand the relationship between the nasal bone and upper lateral cartilage in order to perform nasal surgery safely. Disruption of the keystone area can lead to a collapsed internal nasal valve, saddle nose, inverted V deformity and dorsal nasal irregularities [6]. Therefore, care must be taken when performing dorsal reduction and osteotomies to preserve the keystone area.

The lower vault consists of cartilaginous structures, primarily the lower lateral cartilages and caudal septum. The lower vault defines the nasal tip and changes in the angle and convexity of the domal segments will affect its appearance. Nasal tip stability is dependent on suspensory ligaments between the medial crus and the upper and lower lateral cartilages (so called scroll region) as well as the lower lateral cartilage attachments to the caudal septum at the membranous septum and the inherent strength and shape of the lower lateral cartilages. Anderson’s tripod model of the nasal tip, with the lateral crura representing two legs of the tripod and the paired medial crura composing the central leg, is helpful in visualizing the affects that manipulation of the alar cartilages have on the nasal tip (Figure 2) [7]. The nasal tip can be manipulated in any three dimensional direction by altering one or more of the tripod limbs. Shortening a limb will result in rotation of the tip towards the ipsilateral side as well as deprojecting the tip. While this analogy may be oversimplified, this concept helps surgeons conceptualise maneuvers that alter the shape and position of the tip, including rotation and projection of the tip.

Figure 2. The Anderson tripod model – the medial and lateral crurae of the lower lateral cartilages create a tripod which can effectively dictate tip position depending on changing one or more legs of the tripod.

Understanding the structural framework of the nose is essential in shaping the nose in a stable and functional manner. Additionally, this knowledge allows the surgeon to be cognizant of preserving and improving upon the nasal airway during rhinoplasty. Nasal valves are the narrowest portions of the nasal airway, accounting for over half of the total nasal airway resistance (Figure 3). The area defined as the “internal nasal valve” is the narrowest portion of the nasal airway and it is therefore the primary regulator of nasal airflow. It is the area bound by the nasal septum medially, the caudal edge of the upper lateral cartilage laterally, the floor of the nose inferiorly and the head of the inferior turbinate inferolaterally. The normal angle between the upper lateral cartilage and nasal septum is ten to fifteen degrees and the cross-sectional area of this region is approximately 55–64 square millimeters [8]. A smaller cross-sectional area or a narrowed angle between the upper lateral cartilage and nasal septum may contribute to increased airway resistance and the sensation of nasal airway obstruction.

The “external nasal valve” is located in the nasal vestibule and is bound by the alar rim and columella, including the medial crus, nasal spine and soft tissues covering the nasal sill and floor. The external valve may be narrowed either at rest (i.e., vestibular stenosis) or may have a floppy and weak lateral component (i.e., alar rim) which narrows under the influence of negative pressure during nasal inspiration [9]. In a systematic review of 44 journal articles spanning 25 years addressing nasal valve repair, Rhee et al. showed that correction of nasal valve compromise through rhinoplasty is effective in improving both nasal airflow and quality of life [10]. Understanding the anatomy of the nasal valves and the consequences of their compromise will help surgeons achieve maximal patient satisfaction.

Figure 3. The internal nasal valve. The internal nasal valve is the narrowest area of the nasal airway - the normal angle between the upper lateral cartilage and nasal septum is ten to fifteen degrees, with a cross-sectional area in the range of 55–64 mm².

PATIENT EVALUATION

Proper preoperative evaluation and care is an integral component of the patient's surgical experience and successful outcome [11]. A thorough evaluation of the patient is necessary to maximise the success of surgery. The evaluation process is not merely a physical assessment of the nasal deformity but an opportunity to get to know the patient, their motivations, concerns and expectations. Establishing trust and rapport early is key to successful surgery as it will help the surgeon and patient define realistic expectations and goals of rhinoplasty. Understanding the patient's perception of their nose and its desirable and undesirable qualities will help the surgeon develop a framework for surgical planning. Open communication regarding the patient's motivation for undergoing rhinoplasty is important to establish the psychological and emotional maturity of the patient. A patient's reluctance to openly participate in discussion may signify potential underlying psychological issues that may result in an unhappy patient following what may have been a perfect technical operation [12].

It is important to note that while the surgeon and patient may agree on an aesthetically pleasing nose, many patients may not be able to articulate their preferences or desires satisfactorily [13]. Some surgeons have found the use of photograph editing software to be useful in demonstrating outcomes of rhinoplasty and improving communication of the steps and expectations from surgery. Mehta and colleagues performed a retrospective quantitative analysis of accuracy of preoperative computer images in primary and revision rhinoplasty patients [14]. The investigators demonstrated moderate overall accuracy of preoperative computer imaging, accuracy being greatest along the upper third and worst in demonstrating

supratip height and fullness. Not surprisingly there was a correlation between patient satisfaction and accuracy of preoperatively edited images. Despite the differences in accuracy, most patients found the computer imaging helpful. This result supports a study by Sharp et al. showing significant improvement in satisfaction of patients undergoing cosmetic rhinoplasty following computer imaging compared to those without preoperative imaging [15]. Additionally, a full medical and surgical history is a requisite part of patient evaluation prior to undergoing any surgical planning.

The physical examination of the patient should start with inspection and palpation of the nose to appreciate specific anatomical irregularities. Surgeons must train themselves to look at the patient's nasal surface in the office and identify the underlying osseocartilaginous structures and positions. In addition to the aesthetic qualities of the nose, its functionality should be analyzed during the preoperative examination. The function of the nose as a conduit for respiration should not be overlooked and preserving or improving nasal patency should be a goal in any rhinoplasty procedure. Nasal examination may incorporate anterior rhinoscopy, nasal endoscopy (which may be aided with decongestant spray to assess turbinate hypertrophy) and the Cottle maneuver or external nasal dilator strips for evaluation of nasal valve compromise [16]. Additional objective tests including rhinomanometry, to measure nasal cavity pressure and airflow, and acoustic rhinometry, to analyze nasal cross-sectional area along the length of the nasal airway, may be performed to assess nasal function. Although these steps may help identify possible areas of obstruction, studies have shown that there is not a clear correlation between objective tests such as rhinomanometry or acoustic rhinometry and subjective presence of nasal obstruction or severity of airway obstruction [17]. Therefore, surgical practice cannot be based purely on objective measures such as rhinomanometry and acoustic rhinometry. A graded approach guided by subjective patient complaints along with objective data to guide and measure postoperative success is most beneficial¹, [18].

STRUCTURAL ASSESSMENT

During examination the thickness of skin and soft tissues should be carefully assessed by visualization and palpation. The thickness of skin, subcutaneous fat and nasal muscle are unique to each individual, as shown in cadaveric dissections performed by Anderson [17]. In patients with very thin skin, even minor irregularities of the osseocartilaginous framework of the nose will be easily noticeable, mandating extreme care with skeletal reconstruction to avoid step offs or sharp protrusions. After surgery an unnatural and angular appearance of the nose can occur due to buckling cartilaginous structures under the forces of wound contracture. In contrast, thicker nasal skin with increased sebaceous gland and soft tissues thickness will mask most skeletal imperfections along the dorsum and nasal tip, but may obscure the delicate qualities of the nasal framework resulting in an amorphous appearance, prolonged postoperative inflammation and unsatisfactory long-term outcomes [18]. Thick skin is often associated with a weak and under-projected cartilaginous framework that can make refinement of the nasal tip challenging [19]. It is important to preserve and strengthen the nasal framework in these patients in order to create a desirable and lasting postoperative appearance.

Clinical examination should assess structural integrity of the nose. The nasal tip should be palpated for recoil and cartilaginous integrity. A weak nasal tip suggesting brittle or floppy lower lateral or columellar support will require reinforcement during surgery, whereas a stiff nasal tip may be able to handle more aggressive modifications. Additionally, the length of the nasal bones, the intrinsic strength of the upper lateral cartilages, the support given to the middle third by the upper lateral cartilages and nasal septum and non-visible dorsal irregularities should all be assessed with palpation.

Figure 4. Horizontal thirds and vertical fifths of the face. Each vertical fifth is equal to the width of an eye. The Frankfort horizontal line is a reference line drawn from the superior point of the external auditory canal to the inferior aspect of the infraorbital rim. Horizontal thirds are formed from lines parallel to the Frankfort line at the trichion, glabella, subnasale, and menton.

While rhinoplasty is indeed part art, problem areas of the nose can be defined and structural components analysed in a systematic manner to assess for factors that may lead to real or perceived incongruity or asymmetry [3-20].

The principle of evaluating facial features by division into horizontal thirds and vertical fifths is a useful one (Figure 4). The Frankfort horizontal line, drawn from the superior point of the external auditory canal to the inferior aspect of the infraorbital rim, allows the surgeon to divide the face into three anatomic units by drawing parallels to this line at the trichion, glabella, subnasale and menton (Figure 4). For patients with receded hairlines the middle third is used as the main unit of reference. Vertical fifths are divided with vertical parallel lines, each fifth being equal to the width of an eye. The width of the nasal base should equal a vertical fifth. These reference units are important in noting imbalances that may affect the perception of the nose in relation to the face.

The unique three-dimensional projection of the nose means the rhinoplasty surgeon must study it from multiple angles to understand the interrelationship of structures and the consequences of their manipulation. Viewing the nose from different angles also permits appreciation of the nuanced twists and bumps that may otherwise be missed. It is therefore important to analyze features of the nose thoroughly using standardised views.

STANDARDISED PHOTOGRAPHIC VIEWS

Frontal View

The frontal view permits the best assessment of nasal straightness. A line drawn along the midline from the glabella to the menton should bisect the nose. The brow-tip aesthetic line, which follows the medial eyebrow, curves down the lateral nasal wall and ends at the ipsilateral tip-defining point, should be a smooth symmetric continuous line (Figure 5). Disruption of this curvilinear line will be evident in a crooked or twisted nose [4]. The width of the nose is also best seen on the frontal view. Using the principle of vertical fifths, the alar base should equal one reference unit or the intercanthal distance. The base of the nasal bones should be about three-quarters the width of the alar base.

The frontal view also allows clear assessment of nasal tip shape and symmetry. The nasal tip can present some of the most challenging deformities to correct in rhinoplasty. There are several characteristics that make up complex three-dimensional shape of the tip including the tip volume, definition, width, shape, projection, position and rotation. Patients with excessive tip volume will have a bulbous nasal tip. The vertical and horizontal components of the bulbous tip should be identified. Skin and soft tissue thickness may contribute to nasal tip volume, especially at the alar lobule. Thick sebaceous skin or soft tissue fullness in the interdomal region can give the nasal tip a bulbous appearance.

Figure 5. A line drawn along the midline from the glabella to the menton should bisect the nose. The brow-tip aesthetic line along the medial eyebrow to the ipsilateral tip-defining point should be a smooth continuous line.

The size and shape of the lower lateral cartilages can significantly impact tip bulbosity as well. A bifid nasal tip, excessive lateral crural length, vertical or horizontal convexity of the lateral crura and vertical malpositioning of the lateral crura can all contribute to a bulbous nasal tip. Hafezi and colleagues noted that over forty percent of the 286 rhinoplasty patients in their study had a dome shaped, hemispheric appearance to the lower lateral cartilage at the scroll region which correlated to a strong bulbous nasal tip and nostril flaring [21]. A boxy nasal tip can result from an excessive angle of divergence (greater than 30°) between the two domes, increased domal arch length (greater than 4mm), or a combination of both resulting in widening of the tip defining points ($>5\text{mm}$) [22]. In patients with thin skin, prominent lower lateral cartilage convexity, and wide angle of divergence, a bifid tip may be seen in addition to single tip bulbosity (Figure 6).

Figure 6. The ideal nasal tip should have an angle of divergence less than thirty degrees and interdomal distance of less than four millimetres. Greater angles or distance will result in a bulbous nasal tip.

Finally, the frontal view shows the relationship between the alar rim and infratip lobule, which should resemble a “gull-in-flight” [3]. Asymmetry of the alar rim could suggest alar retraction or malpositioned lateral crura. The relationship of the columella to the alar rim can also be identified from the frontal view, although the lateral view is helpful in this regard.

Lateral View

The lateral or profile view provides important information on tip projection and rotation, dorsal height and profile, alar-columellar proportions and nasal length. Nasal tip projection can be measured as a “3-4-5” right angled triangle as described by Crumley; “3” representing the distance from nasal tip to alar crease, “4” that from alar crease to nasion and “5” that from nasal tip to nasion (Figure 7a), to create a balanced nose [23]. Adequate nasal projection may also be measured using Goode’s method, drawing a perpendicular line to Frankfort’s horizontal plane along the alar crease with second line drawn from the nasal tip perpendicular to this line. The length from alar crease to nasal tip line is divided by the length from the nasion to the nasal tip which should equal 55-60% (Figure 7b) [24]. A third method of assessing projection involves measuring a 1:1 ratio of the distance from the base of the columella to the nasal tip and that of the height of the upper lip from subnasale to the upper

lip vermillion border (Figure 7c) [25]. When assessing nasal tip projection, its relation to other aesthetic facial features such as forehead, cheek and chin projection must also be considered as these may alter the perception of tip projection. Evaluating other facial angles such as Powell and Humphrey's aesthetic triangle (nasofacial, nasofrontal and nasomental angles) will be useful in assessing the true nasal projection compared to the perceived nasal projection relative to other facial features [26].

Figure 7. Nasal tip projection can be analysed using various methods such as those of (a) Crumley, (b) Goode, and (c) Simons.

Rotation is assessed by the nasolabial angle, which is defined by the bisection of a line drawn from the subnasale to the columellar root and a line from subnasale to labrale superius. The ideal angle is typically considered to be 90-100° for males and a more rotated 100-115° for females. Interestingly, Guyuron's studies showed that the ideal nasolabial angle may be more acute and less discrepant between genders than anticipated [29, 30]. Two studies analyzing the aesthetic appearance of nasal tip rotation by altering the nasolabial angle, one surveying the general population and another surveying rhinoplasty surgeons, showed consistent results for the ideal nasolabial angle between both groups: 96° for males and 98° for females, which are more acute than the generally accepted values. The nasolabial angle may be affected by anatomic variables unrelated to the nasal tip such as a prominent anterior nasal spine or maxillary protrusion, so some surgeons prefer to determine tip rotation by measuring the angle between the Frankfort horizontal plane and the long axis of the nostril [28]. Using this measurement, the aesthetic ideal angle ranges from 0-10° in men and 10-25° in women (Figure 8). Abnormalities in nasal tip rotation, especially a ptotic tip, are common indications for tip rhinoplasty. Using the tripod analogy introduced earlier, abnormalities in nasal tip rotation can occur when the strength and integrity of the lateral and medial crura of the lower lateral cartilage is compromised. Additionally, excessive length of the lateral crura or caudal projection of the cartilaginous septum can result in a ptotic tip. The inverse would naturally result in an overly rotated nose. One must be mindful of the attachment of the lower lateral cartilage to the upper lateral cartilage and septum as well as the nasal spine and other minor support structures, which can all, alter tip rotation.

Figure 8. Nasal tip rotation can be determined using the nasolabial angle or nasal-Frankfort horizontal angle.

Continued assessment of the nasal tip should include assessment of the supratip break, tip-defining points and infratip break (Figure 9). There should be a gentle transition between these points. The columella has a double break, the break occurring at the infratip lobule and the second reflecting the columella. These breaks usually mark the junction of the medial and intermediate crus. The lateral view allows for assessment of the alar-columellar relationship (Figure 9). The various relationships between the ala and columella were presented by Gunter et al. [29], who identified positioning of the ala and columella in relation to a line drawn through the long axis of the nose. Ideally, about two to four millimeters of the columella should be visible below the alar margin.

Figure 9. Nasal tip anatomy showing the supratip break, tip defining point and infratip break. Note the double break of the columella (red line): the initial break is at the transition from the nasal tip to the infratip lobule and the second break is at the junction of the intermediate crura and medial crura of the lower lateral cartilages.

Continued evaluation of the nose using the profile view will lead to the assessment of nasal dorsal profile and length. Nasal dorsal assessment should identify any concavity, convexity or contour irregularity along the course of the nose. An aesthetically pleasing nasal dorsum should be a straight line about one to two millimeters posterior to a line drawn from the nasal tip to the nasion. Just superior to the tip defining points should be a slight gentle, one or two millimetre depression corresponding to the supratip [30]. Abnormalities of the nasal dorsum can be due to cartilaginous or bony defects that affect the nasal width, straightness, curvature and projection.

Byrd identified the appropriate aesthetic proportions for nasal length as two thirds of the mid facial height and equal to the chin vertical based on direct clinical measurements taken from 87 models (Figure 10) [31]. However, the length of the nose can be difficult to define due to the many contributing factors that can influence perceived length. The nasofrontal angle converges at the nasion and is typically between 115-130°, with a more obtuse or acute angle more appealing in female and male noses respectively. It is important to remember that a more acute angle may give the appearance of a shorter nose while a shallow angle may appear to lengthen the nose. It is critical to identify the position and height of the nasion to interpret nasal length appropriately. Mowlavi and colleagues [32] surveyed 150 Caucasians on the ideal position of the nasion. For both males and females, the ideal nasion was ten millimetres in height (i.e., anterior to the anterior corneal plane) and positioned above the level of the lower limbus on profile view (Figure 11). A nasion positioned higher will give the appearance of a longer nose while a lower one will give the appearance of a shorter nose with a dorsal hump. Additionally, the relationship of the nasal tip and surrounding facial structures may alter the appearance of nasal length.

Figure 10. Nasal length, as described by Byrd and Hobar, can be characterised as $\frac{2}{3}$ the midface height and equal to the vertical chin height.

Figure 11. Nasion placement is ideally above the level of the lower limbus in both males and females, according to Mowlavi et al.). A nasion positioned higher will give the appearance of a longer nose (blue line) whereas a lower one will give the appearance of a shorter nose with a dorsal hump (green line).

Basal View

The basal view allows evaluation of the nostrils, columella, infratip lobule and alar base. When viewed from the base, the nose can be seen as an isosceles triangle as described by Crumley, which can be divided into thirds [23]. The anterior third is the infratip lobule and the posterior two thirds are the columella and nostrils (Figure 12). The angle of divergence can be measured from this view by identifying the angle between the two domal segments. This is approximately thirty degrees or less. A bulbous or boxy nose would result in a more trapezoidal shape. The basal view allows for another opportunity to assess the symmetry of the lower lateral cartilages by viewing the curvature of the alar rim. The nostrils should be symmetric and shaped like a pear oriented 30-45° from the midline. Asymmetry of the nostrils may suggest domal irregularities or crural height discrepancies. The medial crura of the lower lateral cartilages and the caudal septum can be evaluated for flaring or deviations that may be narrowing the nostril causing airway obstruction. The width of the alar base can be noted from this view and should be approximately equal to the intercanthal distance.

Figure 12. The basal view permits evaluation of the nostrils, columella, infratip lobule and alar base. The nose can be regarded as a truncated isosceles triangle divided into thirds (Crumley). The anterior third is the infratip lobule and the posterior two thirds are the columella and nostrils.

Oblique View

The oblique or three-quarter view is less important for critical structural assessment of the nose but complements the aforementioned views in providing a complete picture of the nose and its relation to other facial structures. Often, patients will consider the oblique view as their profile view when they look in the mirror. On this view, nuances of the nasal dorsal height, length and contour, tip projection and bulbosity and aesthetic brow-tip line may be reassessed.

Using a standardised approach to assessment of the nose will allow the surgeon to thoroughly evaluate all components of the nose to plan a surgery that will help balance the nose with the face. It is important to remember that while there are longstanding ideals for nasal angles, lengths and shapes, studies show that there is variability to these standards and that personal and ethnic considerations must be observed.

RHINOPLASTY APPROACH

Rhinoplasty can be achieved through two main surgical approaches: the endonasal or closed approach; or the external or open approach. Both share many of the same incisions and surgical principles. Incisions include the transcartilaginous or cartilage-splitting, intercartilaginous, marginal and trans columellar types, and can be used alone or combined to provide the necessary exposure. While there are proponents of each approach, there have been few studies comparing them and surgeons should be familiar with both. Experienced rhinoplasty surgeons understand that successful rhinoplasty depends not on the surgical approach used but on understanding of the anatomic diagnosis and preservation of supportive structures [33].

MANAGEMENT OF THE BONY UPPER NASAL VAULT AND NASAL DORSAL REDUCTION

Congenital or traumatic deformities of nasal bones, commonly evident as nasal deviation and dorsal humps, are amongst the most common indications for rhinoplasty. As with much of rhinoplasty there is a paucity of prospective data comparing management of these deformities or surgical techniques.

OSTEOTOMY

Control of the bony nasal dorsum and upper vault often requires osteotomy, to 1) alter the width of the nasal base, 2) close an open roof following dorsal reduction or trauma, or 3) reconcile length and contour differences of the nasal bones [34]. Lateral, medial and intermediate osteotomies are used to manipulate the nasal bones (Figure 13). The ideal osteotomy should be precise, reproducible, safe, and afford maximal aesthetic and functional

results. Additionally, it should limit the postoperative sequelae of edema, ecchymosis and nasal bone instability [35].

Figure 13. Medial (1), lateral (2) and intermediate (3) osteotomies can be used to manipulate the nasal bones.

Lateral osteotomies are the most commonly used in both functional and aesthetic correction of nasal deformities. Two basic techniques in performing lateral osteotomies have become accepted over the years: continuous and perforating. Both techniques aim to mobilise the lateral upper nasal vault through a “high-to-low-to-high” approach described by Webster, maximizing nasal bone mobility while maintaining structural integrity of the nasal airway [36]. The continuous lateral osteotomy is performed endonasally starting at the pyriform aperture, creating a single fracture line along the ascending process of the maxilla and nasal bone. The perforating osteotomies are performed through a percutaneous external or transnasal internal approach by creating multiple postage stamp-like osteotomies along the intended line of mobilization. The fracture is completed by digital or instrument assisted mobilization of the nasal bones.

There have been multiple studies comparing the two techniques of lateral osteotomies. Zoumalan et al. quantitatively evaluated the effects of both continuous and perforating lateral osteotomies on nasal bone narrowing, showing no statistical difference in the dorsal or ventral nasal bone width following narrowing. Thus both methods are able to achieve satisfactory control of the upper vault. Gryskiewicz and Gryskiewicz performed a prospective, randomised, partially blinded study of 75 patients comparing postoperative ecchymosis and edema between perforating and continuous lateral osteotomies, showing statistically significant differences favoring perforating osteotomies [38]. Additionally, a cadaveric study of nasal mucosal trauma following lateral continuous osteotomy compared to percutaneous external osteotomy by Rohrich et al. showed that there was nearly a seven-fold increase risk of mucosal injury using the continuous approach [39]. It is important to note that while osteotomy technique and size of osteotome are contributing factors to postoperative edema

and ecchymosis, these are not the only factors. Critics of the perforating lateral osteotomies argue of the risk of perceptible cutaneous scarring following surgery. Gryskiewicz [40] and Hinton et al. [41] showed that visible scarring occurred in up to six percent of patients six months to one year following surgery with one patient (two percent) requiring additional scar revision. A critical review of these studies shows that both methods provide excellent mobilization of the bony nose with no significant differences in aesthetic or functional outcomes but perforating osteotomies may provide decreased postoperative sequelae of edema and ecchymosis with little risk of perceptible scarring.

Medial osteotomies may be required in cases of significant bony deviation or when the width of the nasal dorsum requires complete mobilization of the nasal bones. The osteotomy frees the nasal bone from the bony septum medially and the nasal root superiorly by either directly intersecting with the fracture line of the lateral osteotomy or creating a fault along the nasal bone that will result in a predictable fracture following lateral osteotomy. The medial osteotomy can be performed in a straight, oblique, or perforating manner. Harshbarger and Sullivan suggest performing medial osteotomies at fifteen degrees laterally of the midline to follow the natural break-line of the nasal bones [42]. Care must be taken during medial osteotomy to avoid superior extension into the thick bone at the nasofrontal suture line, which can cause a rocker deformity requiring further osteotomies to correct.

Intermediate osteotomies may be required in cases of severe concavity and convexity or significant length discrepancy resulting in deviation of the nasal bones. If required, the intermediate osteotomies should be performed prior to mobilizing the nasal bones through lateral osteotomies. These osteotomies are usually performed in a continuous fashion from caudal to cranial along the region of greatest deformity. In laterally occurring deformities, the intermediate osteotomies may be performed through a percutaneous external approach as described by Westreich and Lawson [43].

NASAL DORSAL HUMP REDUCTION

The surgical technique chosen for hump removal is determined by the degree and location of dorsal hump projection. Often the dorsal hump has a cartilaginous and bony component. Dorsal hump reduction of the bony nasal dorsum is usually performed with an osteotome or rasp, and use of an ultrasonic bone aspirator has also been described [44]. The cartilaginous nasal dorsum is generally reduced and contoured using a scalpel and/or osteotome. Lee et al. performed a systematic review of nasal dorsal reduction surgery showing only retrospective evidence over the past decade [45]. No consensus methodology for removing the dorsal hump emerged from the eleven studies reviewed, with most surgeons using multiple surgical techniques including reductive osteotomies and rasping. Surgeons reported good outcomes and minor complication rates of 0-26% - mostly prolonged edema and hump underresection [45]. Dorsal hump reduction can be performed en bloc or as a split approach addressing cartilaginous and bony portions individually. Care must be taken not to disrupt the upper lateral cartilage attachment to the caudal nasal bone during the reduction in order to avoid postoperative complications of inverted-V deformity and nasal sidewall instability. The technically challenging aspect of dorsal reduction is achieving the ideal nasal profile with respect to the patient's face while maintaining key structural support of the nose.

MANAGEMENT OF THE MIDDLE NASAL VAULT AND NASAL DORSAL AUGMENTATION

The middle nasal vault houses the upper lateral cartilage and cartilaginous septum. Surgical techniques aimed at management of deformities of the middle nasal vault have evolved over the past ten to fifteen years due to an increased awareness of function of the internal nasal valve as a regulator of airflow [46-51]. Maintaining the stability of the middle nasal vault is imperative in any rhinoplasty procedure. The integrity of the connections between the upper lateral cartilage and the dorsal septum medially, the nasal bone at the keystone region and the lower lateral cartilage at the scroll region will help avoid postoperative complications such as saddle nose deformity, inverted-V deformity, hourglass deformity, dorsal irregularities, or nasal valve collapse. Many of the surgical techniques that have been described for management of the middle nasal vault have focused on secondary nasal surgery to improve nasal function following rhinoplasty [49, 52-54]. The overall goal of rhinoplasty addressing the middle nasal vault is to strengthen the structural support elements and balance the aesthetic requirements with nasal function.

SPREADER GRAFTS AND FLAPS

In the 1980's Sheen popularised the use of spreader grafts as a means of reconstructing the internal nasal valve and contouring the nasal dorsum of the middle nasal vault [54]. Since then, spreader grafts have become widely used in primary and secondary rhinoplasty to widen the internal nasal valve in static or dynamic nasal valve collapse, prevent nasal valve collapse following dorsal hump reduction and recontouring or straightening the nasal dorsum [54, 55]. The spreader grafts should be placed under the nasal bones and cover the keystone area and be long enough to extend to the caudal edge of the upper lateral cartilage. Spreader grafts may be made from septal cartilage, but in cases of previous surgery where inadequate septal cartilage remains, conchal cartilage or rib cartilage may be used (Figure 14). Alternatively, in patients with a prominent dorsum who are undergoing dorsal reduction, the upper lateral cartilage excess may be folded on itself to lie between the septum and upper lateral cartilage to serve as an "auto-spreader graft", or so-called "spreader flap" [56, 57]. Occasionally, wider grafts may be required due to insufficiency of lateral cartilage or nasal deviation in which case multiple pieces of cartilage may be layered to provide adequate thickness for appropriate nasal contouring and support.

While the use of spreader grafts is widespread, there remains a lack of strong supportive evidence for their use in rhinoplasty. Rhee et al. noted through systematic review that most studies on the management of nasal valve collapse, including the use of spreader grafts, were uncontrolled case series [10]. However, despite the lack of well-designed studies, there appears to be an abundance of anecdotal clinical evidence suggesting that spreader grafts are beneficial in improving nasal aesthetics and function [58]. Spreader grafts have been shown to improve both objective and subjective measures of nasal airflow as assessed by rhinomanometry, acoustic rhinometry and validated outcome measures including the Nasal Obstruction Symptom Evaluation (NOSE) scale and Visual analog scale (VAS) [56, 59-62].

Figure 14. Spreader grafts are essential in supporting and reconstructing the middle nasal vault. They may be fashioned in strips from autologous cartilage and placed between the upper lateral cartilage and nasal septum.

INTERNAL NASAL VALVE SURGERY AND FUNCTIONAL RHINOPLASTY

The internal nasal valve is of great significance to rhinoplasty involving manipulation of the middle nasal vault. Since the introduction of the spreader graft many other techniques have been reported. In 2004 Andre et al. presented the endonasal placement of spreader grafts which may have some advantages in certain patient populations due to its limited invasiveness, but no studies comparing the open and endonasal approach have been performed [63]. Other variations of the spreader graft including spreader flaps [56], auto-spreader grafts [64] and mini-spreader flap [61] techniques have all been shown subjectively to relieve nasal obstruction and objectively to increase nasal airflow on by increasing the nasal valve angle.

The ability of spreader grafts to support and lateralise the lateral nasal wall may be limited in patients with weak nasal sidewalls. In such patients a lateral crural strut graft or alar batten graft may be required, as reported by Faris et al., to add stability and support of the lateral nasal wall (Figure 15) [65]. In cases of significant lateral nasal sidewall instability or need for additional nasal valve support, the alar batten graft can be used with good success. Toriumi first described the use of the alar batten graft, placement of small strips of cartilage in subcutaneous pockets, to strengthen the lateral nasal wall [66]. There have been numerous retrospective studies looking at subjective assessment of nasal patency following rhinoplasty with alar batten graft for management of nasal valve collapse, showing an overall 96-100% improvement in subjective nasal airflow over a one to five year follow-up period [62,66-68]. The alar batten graft has become a widely used adjunct to the spreader graft in management of nasal valve collapse in rhinoplasty with good functional and aesthetic outcomes.

Figure 15. Patients with weak nasal sidewalls may require additional structural grafts for support. Batten grafts, shown in various positions here, can provide strength and stability to the nasal sidewall and prevent dynamic collapse on inspiration.

The upper lateral cartilage splay graft initially described by Guyuron in 1998, which uses conchal cartilage placed over the dorsum of the septum and under the upper lateral cartilage, can also be used to reconstruct the middle vault and give significant support to the internal nasal valve [69]. Additionally, the butterfly graft, introduced by Clark and Cook, using conchal cartilage as an onlay graft secured to the caudal margin of the upper lateral cartilage, can help spring open the internal nasal valve [53]. Friedman and Cook [70] reviewed 100 primary rhinoplasty patients with internal nasal valve collapse who had undergone conchal butterfly grafts. Internal nasal valve collapse was identified by preoperative relief of nasal obstruction via Cottle maneuver or application of an external nasal dilator, collapse of nasal sidewall on inspiration, or weak upper lateral cartilage support on palpation. The investigators found that over 90% of patients reported subjective improvement in breathing and 88% of the patients were happy with their postoperative appearance.

While studies looking at the splay and butterfly grafts were retrospective and did not use validated outcome measures, they appear to be a viable option for functional rhinoplasty in appropriate patients. However these grafts can significantly widen the middle vault, resulting in unacceptable cosmetic results. Deylaminour reported as many as twenty percent of patients being unhappy with their cosmetic outcome from this maneuver suggesting conscientious patient selection for this grafting technique [71].

Flaring sutures described by Park [72], thrown from one upper lateral cartilage to the other and tied tightly over the nasal dorsum, or nasal valve suspension sutures as described by Paniello [48], anchoring the collapsed nasal valve to the inferior orbital rim, can be used alone or in conjunction with other techniques to widen the internal nasal valve [72]. Schlosser and Park [76] investigated the effects of spreader grafts, flaring sutures or a combination of both on the nasal airway of six cadavers, using acoustic rhinometry to measure the nasal airway before and after treatment. Both techniques in isolation failed to have a statistically significant impact on minimal cross-sectional area of the nasal valve (5.4% for spreader graft

and 9.1% for flaring sutures) but a combination of the two significantly increased minimal cross-sectional area by 18.7% ($p < 0.05$). This finding was consistent with retrospective reviews by Sciuto and Bernardeschi [77] and Park [75], showing that patients with internal nasal valve collapse who underwent rhinoplasty with combined spreader grafts and suture techniques experienced improved postoperative subjective nasal patency.

Armed with a better understanding of the nasal valve, recent refinements in surgical techniques and an accompanying thorough preoperative evaluation, surgeons will be able to identify and treat nasal valve collapse. Carefully selected functional nasal surgery with correction of nasal valve dysfunction has been shown to improve quality of life significantly in patients complaining of nasal obstruction with preoperative findings of nasal valve collapse [59,75].

NASAL DORSAL AUGMENTATION

Nasal dorsal augmentation can be a challenging problem to address in the middle nasal vault. A wide array of techniques have been implemented in dorsal augmentation including en bloc cartilaginous augmentation, diced cartilage with fascial or alloplastic grafts, soft tissue augmentation and alloplastic implantation. Generally, autogenous cartilage grafts either from the nasal septum, ear or costal cartilage is preferred over irradiated rib cartilage or alloplastic grafts due to perceived resistance to resorption and warping. However, the data supporting these perceptions were based on low-level evidence with small data pools, inconsistent study designs and limited follow-up [76]. Lee et al. showed in their systematic review of nasal dorsal augmentation that graft resorption, infection and revision rates were comparable regardless of donor cartilage used [45]. Kriedel and colleagues [80] performed a long-term study of 357 patients who underwent primary or revision rhinoplasty with 1025 irradiated homologous cartilage grafts (IHCC) and 218 autogenous cartilage grafts. The total complication rate, including warping, infection, and resorption related to the irradiated homologous cartilage grafts, was 3.25% and the overall comparative resorption rate between autologous cartilage versus irradiated homologous cartilage was nearly identical (1.37% to 1.01% respectively). It was not methodologically possible to compare complication rates of IHCC and autogenous cartilage groups directly as both types were often used together (the authors attributing all infections to have arisen from the IHCC graft in such cases).

Literature supports the use of irradiated homologous cartilage graft as a viable option to autogenous cartilage grafts for nasal dorsal augmentation.

ALLOPLASTIC IMPLANTS

Synthetic implants have long been a topic of controversy in rhinoplasty. Critics cite concerns with the introduction of foreign material and risks of inflammation, infection and extrusion. Peled et al. reported their findings from a meta-analysis of the three most commonly used implants in rhinoplasty - silicone, expanded polytetrafluoroethylene (Gore-Tex) and porous high-density polyethylene (Medpor), showing that silicone had twice the rate of implant removal compared to polytetrafluoroethylene and high-density polyethylene (6.5%

vs. 3.1%) [78]. Other studies have shown that complication rates were low but not negligible - for instance, extrusion (1-10.7%), infection (1-6.25%) and displacement (1-3%), and were higher in revision rhinoplasty cases [79-85]. Recently, more literature has appeared supporting the use of resorbable synthetic material, specifically, polydioxanone (PDS) plates in septal reconstruction. James and Kelly reported on 58 primary and secondary rhinoplasties using the PDS plate in conjunction with autogenous cartilage grafts for floating columellar strut, septal extension grafts and alar batten grafts, showing good postoperative results [86]. Only minor complications of infection (1.7%) and partial extrusion (1.7%) were noted after a mean follow-up period of eighteen months. An additional retrospective study of 400 patients by Boenisch in the use of PDS plates for reconstruction of severe septal deformity showed that nearly ninety percent subjectively maintained a straight nasal septum after twelve months, correlating with over eighty percent objective improvement in nasal rhinomanometry [87]. There appears to be retrospective evidence supporting the use of resorbable PDS plates in septal reconstruction. However, alloplastic implants will continue to be a topic of controversy that requires more prospective data and better long-term evidence. In the future, new synthetic materials may become available for implantation that will continue to evolve the field of nasal augmentation.

MANAGEMENT OF THE LOWER NASAL VAULT AND NASAL TIP SURGERY

The lower nasal vault consists of the lower lateral cartilage and caudal nasal septum forming the nasal tip. The complex three-dimensional nature of the nasal tip makes it one of the most challenging aspects of rhinoplasty. Tip projection, rotation and refinement are frequently discussed in rhinoplasty literature with a myriad of surgical techniques and management philosophies. As with most of rhinoplasty, strong evidence does not exist for the many different suture and grafting techniques for tip rhinoplasty and most of the available data is in the form of retrospective series.

Over the years, nasal tip surgery has moved away from reductive techniques such as cartilage morselization, scoring and resection and focused on tip stabilization and maintaining or augmenting supportive structures of the nasal tip as surgeons have realised the long-term consequences of wound contracture and gravity. Suturing and grafting techniques to help contour and stabilise the nasal tip have been evolving and are widely used by rhinoplasty surgeons.

Tip suture techniques can effectively control the shape and curvature of the lateral cartilages while maintaining their structural integrity. Variations of the transdomal and interdomal suturing techniques have been described to address the bulbous tip [88, 89]. Gruber proposed a step-wise suturing algorithm based on 150 rhinoplasty cases for the bulbous nasal tip in which cephalic resection, transdomal and interdomal sutures, lateral crural mattress sutures and columella-septal suture are placed to create tip contour and address tip bulbosity [90].

Tip grafting techniques can be used in instances where greater projection of the nasal tip is required than can be produced with suture techniques, when camouflage of persistent

asymmetry is needed, when added bulk is required at the infratip lobule region, or when greater refinement of the lobule is required than conventional techniques can provide [91].

Prior to working on the nasal tip, the nasal base should be assessed for stability to ensure a solid foundation for the lower nasal vault and prevent postoperative loss of tip projection and/or rotation [92]. If needed, a columellar strut or caudal extension graft should be implemented to support the medial crura of the lower lateral cartilage. Additionally, based on a review of 100 consecutive primary rhinoplasty patients, Constantian [93] purports that rhinoplasty surgeons should identify two key anatomical characteristics that will ensure successful tip surgery and avoid secondary deformities: 1) whether there is adequate tip projection and 2) whether the lateral crura are malpositioned. He noted that over sixty percent of patients required increased tip support and projection and nearly half (46%) had anatomical variants of alar cartilage positioning [93]. Therefore preoperative identification and surgical planning to support and reinforce the nasal tip is important for long-term surgical success.

TIP REFINEMENT

The bulbous or amorphous nasal tip will require refinement techniques to achieve satisfactory contouring. The shape and position of the lower lateral cartilages along with the thickness of the overlying skin and soft tissue envelope determine tip width and bulbosity. The thickness of the skin will heavily influence the choice of surgical technique. Due to the complex nature of the tip bulbosity, a graduated approach to nasal tip refinement should be used. The surgical approaches to addressing the cartilaginous components of a bulbous tip include cephalic resection, suture techniques to refine the tip and flatten the lateral crura, grafting techniques to mask or augment the nasal tip, domal or lateral crural division and lateral crural repositioning.

Patrocinio et al. retrospectively reviewed 641 rhinoplasty cases over a three year period to present a graduated approach to tip rhinoplasty based on the level of tip bulbosity comparing methods of tip refinement including cephalic trim, interdomal suturing with or without lateral crural steal, shield grafting and vertical dome division [94]. They reported an overall patient satisfaction rate of 95.6% and revision rate of 5.6%. Patients with mild tip bulbosity but excellent medial and lateral tip support did well with conservative cephalic trim without delayed postoperative loss of tip projection. Patients with an abnormally large angle of divergence between the medial and intermediate crura (more than thirty percent) or excessive interdomal width (more than four millimetres) required interdomal suture techniques [95]. Patients with thick skin and weak lower lateral cartilages required extended shield grafts to achieve satisfactory refinement, while thick skinned patients with strong lower lateral cartilages benefited from dome division techniques. The study demonstrated a graded approach to the nasal tip that could help surgeons achieve optimal long-term success in tip refinement.

POSTOPERATIVE CARE

Appropriate postoperative care is essential for proper healing and successful long-term outcomes after rhinoplasty. Appropriate care involves nasal splinting, taping and packing, nasal hygiene, perioperative antibiotics and strategies to minimise edema. There have been many methods of postoperative external nasal splinting that have been described using different material including aluminum, plaster and dental compounds [96, 97]. Regardless of the material used, the primary goal of external nasal splinting is to provide a secure bolster for the nasal framework and soft tissue envelope following rhinoplasty [98]. Prior to application of the external nasal splint, the nasal dorsum is taped to limit postoperative edema and prevent irritation from the splinting material. There are proponents of endonasal septal splints or packing for patients who have had septoplasty as part of their rhinoplasty procedure to help with septal mucosal flap approximation and prevent recurrent/secondary septal deviation, septal hematoma or synechiae formation [99,100]. However, Cook et al. showed in a prospective study of 100 patients undergoing septoplasty that patients who were randomised to have silicone septal splints did not demonstrate any such benefits but did have significantly increased postoperative discomfort [101]. The use of septal splints following septorhinoplasty is therefore not universally recommended and the decision should be made on a case by case basis.

Nasal hygiene is imperative in maintaining a clean surgical site. This will help prevent nasal crusting and infection, which can lead to inflammation and scarring. Use of nasal saline spray will help maintain a moist nasal airway to promote healthy mucosal healing. Although there is a lack of evidence supporting the use of nasal saline following rhinoplasty, there is abundant empirical evidence supporting its use. Shone et al. [102] showed persistent decreased mucociliary clearance three weeks after septoplasty and Tomooka and colleagues' found a statistically significant improvement in nasal symptoms amongst patients with nasal dysfunction using nasal saline irrigation [103]. Thus there is indirect support for the use of nasal saline following rhinoplasty.

Postoperative edema is inevitable after rhinoplasty. There is conflicting data on the efficacy of routine systemic corticosteroid administration for prevention and mitigation of postoperative edema. Kara and Gokalan conducted a double-blind, randomised controlled trial with placebo control to evaluate the effects of single-dose dexamethasone on eyelid edema and ecchymosis following rhinoplasty [104]. They determined that single-dose dexamethasone had a significant effect in decreasing upper and lower eyelid edema and upper eyelid ecchymosis for the first two days. Hoffman and colleagues showed in their randomised, double-blind study of intraoperative intravenous dexamethasone plus a five day postoperative course of oral prednisone following rhinoplasty that there was significantly less postoperative eyelid and paranasal edema during the first four days after surgery in those patients receiving steroids [105]. A meta-analysis performed by Hafez et al. concluded that preoperative steroid dosing is superior to postoperative dosing and extended dosing superior to a single dose in reducing periorbital edema and ecchymosis after rhinoplasty [106].

While steroids may decrease early facial edema, they appear less effective in reducing nasal edema. A study conducted by Berinstein et al. did not show any significant improvement in nasal edema, determined using magnetic resonance imaging, after rhinoplasty with osteotomies in patients who received steroids preoperatively versus those who did not

[107]. Thus although evidence suggests that perioperative and postoperative corticosteroids decrease early facial edema, the effects appear short-lived and do not translate to intranasal swelling. Given the inherent risks of corticosteroid use, surgeons should weigh their risks and benefits for individual patients prior to administration following rhinoplasty.

Whether an open or closed approach is used for rhinoplasty, proper care of the incision site will decrease the risk of infection and help minimise scar formation. Topical and systemic antibiotics are frequently used postoperatively in rhinoplasty. Bandhauer et al. showed topical antibiotic ointment to decrease the growth of potentially infectious nasal flora and *Staphylococcus aureus* in patients with nasal packing [108]. Randomised, controlled trials have shown that prophylactic systemic antibiotics within two hours of the start of surgery have been effective in preventing postoperative infections in various surgical procedures [109]. There are no guidelines regarding routine postoperative systemic antibiotics after nasal surgery. However, most rhinoplasty surgeons prefer to give postoperative antibiotics to prevent toxic-shock syndrome in the setting of intranasal splints or packing, the exposure of soft tissues to the nasal airway and the use of devascularised cartilage or synthetic grafts during rhinoplasty [110].

COMPLICATIONS OF RHINOPLASTY

Careful preoperative and intraoperative assessment and patient education will optimise the surgical outcome. As with all surgical procedures, complications may occur following rhinoplasty. Surgical experience will help the surgeon anticipate which intraoperative maneuvers may lead to postoperative issues. In addition, a thorough awareness and knowledge of the possible complications allow the surgeon to identify and treat them should they arise. Postoperative complications of rhinoplasty may be categorised as either early (up to six weeks postoperatively), or late (occurring after six weeks).

Intraoperatively the surgeon may be faced with unexpected excessive bleeding, which may be due to inadequate local hemostatic injections, intraoperative hypertension, undisclosed use of anti-platelet or anti-thrombotic agents, or underlying coagulopathy. Careful use of electrocautery and topical vasoconstrictive medication may be required. Care must be taken during elevation of the skin and soft tissue, especially in thin-skinned patients. Inadvertent violation of the skin can lead to unsightly and act as a conduit for infection.

Complications can arise from manipulation of weak or unstable osseocartilaginous structures, including collapse of the bony pyramid or disarticulation of the upper lateral cartilages from the nasal bone. Careful reapproximation and use of grafts to provide support to these structures may be necessary. Improperly placed or inadequate osteotomies can lead to deformities such as the rocker deformity (following incomplete medial osteotomies), requiring percutaneous completion of the osteotomy and careful alignment of the nasal bones; the open roof deformity (from incomplete joining of medial and lateral osteotomies); and step deformities (due to misplaced lateral osteotomies) [111, 112]. The surgeon must also be mindful of the vital surrounding structures (i.e., orbit, nasolacrimal system, cranium) that may be injured during osteotomies [113].

In the early postoperative period the surgeon should be aware of potential bleeding and infectious risks [114]. Nasal packing and postoperative antibiotics may be used to avoid some

of these early complications. In cases of infection, early treatment with systemic antibiotics and incision and drainage of any abscesses are important in preventing serious complications. Some nasal edema and ecchymosis may be expected after nasal surgery. Careful taping and splinting of the nose will help minimise nasal edema. Cold compresses, postoperative head elevation and hypertensive control can all help decrease the severity and length of edema and ecchymosis postoperatively. In instances of severe edema, postoperative oral and injectable steroids may be useful.

Early postoperative success unfortunately does not always portend long-term success. Late complications occurring after six weeks postoperatively can manifest as a functional and/or cosmetic failure. Late complications often arise as sequelae of the healing process including scar formation and bony and cartilaginous remodeling and resorption [115]. Overly aggressive resection of the bony or cartilaginous structures during rhinoplasty may result in a weakened and malpositioned framework.

Late complications can be considered based on the respective nasal vaults involved. The bony nasal vault may exhibit asymmetry or widening due to inadequate or misaligned osteotomies, saddling due to over-reduction of the dorsal nasal bone, persistent dorsal hump, step deformity and open-roof deformity [116]. Middle third deformities include the inverted-V deformity from disarticulated or weakened upper lateral cartilages, pollybeak deformity from soft tissue edema or hypertrophy or loss of tip projection, saddle nose deformity from over-resection of the dorsal septum, and nasal asymmetry [116, 117]. Late complications of the lower third or nasal tip may present as tip distortions including tip asymmetry, bossa formation, tip widening or pinching and tip over- or under-rotation. The aesthetic relationship between the ala and columella may be affected (i.e., alar notching, hanging columella, etc.) by the over- or underresection of the lateral crura of the lower lateral cartilage and the caudal septum [118, 119]. Furthermore, the functionality of the nose may be compromised with late complications such as internal and external nasal valve collapse (static or dynamic) due to over-resection or inadequate support [120, 121]. Additionally, septal perforations, synechiae/webbing and nasal stenosis can have disastrous late consequences in nasal functionality and cosmesis [121, 122].

Late postoperative complications usually require revision rhinoplasty to correct the nasal deformities. Therefore, care must be taken during the primary surgery to consider and address potential pitfalls and long-term sequelae of each surgical maneuver. The downstream effect of each maneuver on the functionality and cosmesis of the nose must not be overlooked and will be better understood as the surgeon critically appraises their own experience over the years.

CONCLUSION

Rhinoplasty is a complex procedure involving a balance between form and function. The primary goal is to achieve the patient's desired aesthetic outcome while maintaining or improving nasal breathing. To achieve satisfactory outcomes, a thorough understanding of the patient's nasal anatomy and the surgical techniques needed to correct the irregularities is essential. The most important advice is perhaps to manage the patient's expectations before and after surgery by maximizing the time spent in the office counselling the patient and minimizing the complexity of the surgical intervention required to achieve the patient's

desired outcome. It is important to develop excellent rapport with the patient to develop a clear, common vision of the final surgical outcome. Proper preparation and patient evaluation allows one to choose the most appropriate surgical approach and technique to achieve a desirable outcome. Finally, meticulous surgical execution that is grounded in clinical evidence will allow for the best long-term outcome. While much of rhinoplasty is based on historical retrospective data, improvements in outcomes research of patient satisfaction based on validated outcome measures along with improved study design and prospective, long-term data will help rhinoplasty surgeons continue to evolve and perfect their craft.

Chapter 34

MASTOPEXY

Daniel Marsh* and Niri Niranjana

St Andrews Centre for Plastic Surgery, Broomfield Hospital,
Chelmsford, UK

KEY POINTS

- The mastopexy procedure is a compromise between the final aesthetic result and scarring that is acceptable to the patient.
- In choosing a mastopexy technique the surgeon must account for the parenchymal distribution in relation to the inframammary fold and the quality of the overlying skin envelope.
- If considering a periareolar technique do not attempt to lift the nipple more than four centimetres.
- From his large series of vertical scar mastopexy procedures, Lassus suggests a superior pedicle is acceptable if moving the nipple nine centimetres or less, otherwise a lateral pedicle should be used.
- Mastopexy augmentation is a difficult procedure accompanied by an 8-23% reoperation rate (in two large single surgeon series) and an 11-17% complication rate.

INTRODUCTION

Literally ‘breast fixing’, mastopexy refers to the surgical technique for uplifting the breast. This chapter reviews the background and evidence for common mastopexy procedures.

HISTORY

There are numerous descriptions of mastopexy techniques in the literature dating back to Schwarzmann [1] who described the dermal pedicle for breast reduction and Lamont [2] who in 1946 described a two-stage mastopexy for markedly enlarged breasts. Considering all the available mastopexy techniques, the choice of which to use depends on the degree of ptosis, amount of available breast tissue/skin excess and a compromise between eventual cosmetic result and the degree of scarring acceptable to the patient. Here we will review the most common mastopexy procedures divided into type by incisions used and the evidence behind their use.

Although many mastopexy procedures have evolved from breast reduction techniques, especially in terms of preserving the blood supply to the nipple with various designs of pedicle, mastopexy is distinct from breast reduction in that the aim is to preserve as much parenchymal tissue as possible.

ANATOMY

The footprint of the breast on the chest wall typically sits between the sternal edge and the mid axillary line and from the second to the sixth rib. The mammary gland sits in a relatively avascular plane superficial to the anterior thoracic wall. The gland itself consists of between fifteen and twenty lobes of varying numbers of lobules each with a single lactiferous duct opening into the nipple. The lobes are separated by fibrous septae running from pectoral fascia to the dermis of the skin envelope. In the upper portion of the breast these septae are known as the suspensory ligaments of Astley Cooper and help suspend the breast on the chest wall. A non-lactating breast consists of fibrous fatty tissue held between the fibrous septi running between the pectoralis fascia and the skin envelope. After lactation and the menopause there is resorption of the glandular tissues, which is one of the causes of breast ptosis. The breast is supplied by perforating vessels from the internal mammary artery, the lateral thoracic artery and intercostal vessels (Figure 1). Venous drainage of the breast is through vessels accompanying the arteries - mainly internal mammary and lateral thoracic veins.

Any mastopexy procedure that lifts the nipple requires separation of the nipple from the surrounding skin on a dermal or parenchymal pedicle, and the design of the pedicle must take into consideration the source of the blood supply to the nipple. If the mastopexy procedure uses a superior or lateral pedicle the nipple blood supply will be from the thoracoacromial and/or lateral pectoral vessels. A medial pedicle utilises the blood supply from the internal mammary vessels and a central or inferior pedicle the intercostal perforators.

The nerve supply to the breast is derived from the second to sixth intercostal nerves [3], with the nipple and areola consistently innervated by the lateral and anterior cutaneous branches of the third, fourth and fifth intercostal nerves (Figure 2). In a cadaveric study looking at breast specimens of 28 females the most constant innervation pattern was by the 4th lateral cutaneous branch (79%) and by the third and fourth anterior cutaneous branches (57%) [4]. Sensation to the upper pole of the breast is from supraclavicular branches of the cervical plexus.

Figure 1. The arterial supply of the breast.

Figure 2. Innervation of the breast.

The ‘perfect breast’ was defined in 1955 by Penn [5] as having a sternal notch to nipple distance of 21cm which is also equal to the distance between the nipples. The nipple to inferior mammary fold distance was defined as 6.8cm and the areolar diameter 3.8-4.5cm. Although these measurements are still oft quoted, it should be remembered that this study was based on measurements taken from only twenty women whom the author determined had ‘aesthetically perfect’ breasts. Clearly these measurements cannot be applied across all cultures and to women from all societies as the ‘perfect breast’ in one culture may be viewed as too large or small in another.

A sound knowledge of breast anatomy is essential when considering patients for a mastopexy procedure which requires uplift of the nipple-areola complex to its normal position, rearrangement of breast parenchyma and redraping of the breast skin over the breast mound after resection of any excess skin.

INDICATIONS FOR MASTOPEXY

One of the most common indications is the post childbirth/breast feeding breast when the breast may be drooping and appear deflated as compared to the prepregnancy state. Other indications are simple ageing of the breast, the effects of gravity and weakening of the supporting tissues of the breast.

In more recent times patients who have had gastric banding procedures leading to massive weight loss commonly request mastopexy and these can be some of the most challenging cases as the nipple can be as much as forty centimetres below the sternum. Further, with the improvement in breast cancer survival there is an increasing patient population who require contra lateral symmetrising mastopexy procedures following breast reconstruction.

Patients with congenital breast deformities such as breast asymmetry or the tuberous breast could also be considered as requiring a mastopexy procedure where the shape of the breast is altered. Further, mastopexy procedures may also be combined with augmentation of the breast – the so called ‘mastopexy-augment’, commonly referred to as ‘the most difficult procedure in aesthetic breast surgery’ with a reputation for being the ‘most frequently litigated operation in plastic surgery’ [6].

CLASSIFICATION OF BREAST PTOSIS

The aim of mastopexy is to address breast ptosis as originally described by Regnault [7] who graded breast ptosis depending on the relationship between the nipple and the inframammary fold (IMF) (Figure 3).

Grade 1 – nipple at the level or just inferior to the IMF

Grade 2 – nipple is 1-3cm below the IMF

Grade 3 – nipple is more than 3cm below the IMF

Figure 3. Breast ptosis according to Regnault 1976, before and after mastopexy.

Since 1976 the category of pseudoptosis has been added to Regnault's original grading system referring to the situation where the nipple is at or above the IMF but the majority of breast tissue is below the IMF.

Brink [8] recognised the importance of both the breast parenchyma and the nipple position in his classification of ptosis into glandular ptosis, true ptosis, pseudoptosis and parenchymal maldistribution (Figure 4).

Figure 4. Classification of breast ptosis according to Brink: A) glandular ptosis; B) true ptosis; C) parenchymal maldistribution; and D) pseudoptosis.

When considering the degree of ptosis and the appropriate mastopexy technique, the position of the inframammary fold should also be taken into account as true breast ptosis involves three elements: skin laxity, migration of the nipple areolar complex and the position of the inframammary fold – that is, the IMF itself can be adjusted which will also have an effect on ptosis.

APPRAISAL OF THE EVIDENCE LEVEL FOR MASTOPEXY

When examining the evidence for surgical techniques, it would be preferable to use at least Level II evidence (see Appendix). This level of evidence is too sparse for mastopexy procedures and there are certainly no randomised controlled studies or meta-analysis of randomised controlled studies (Level I). Level III evidence is defined as that which is obtained from well-designed non-experimental descriptive studies such as comparative studies, correlation studies and case studies; Level IV evidence is that from expert opinions and clinical experience of respected authorities.

A search of the Cochrane database in February 2013 using the term ‘mastopexy’ produced only two studies, one comparing two types of local anaesthetic [9] and the other looking at occurrence of sebaceous cysts at the incision site of mastopexy procedures [10]. Entering the term ‘mastopexy’ into Pubmed produced 424 results; applying the filters ‘clinical trial’, ‘comparative study’, ‘controlled clinical trial’, ‘multicentre study’, ‘randomised controlled trial’ reduced the 424 results down to twenty results, of which only one by Swanson [11] was reporting on mastopexy, the other studies being about breast reduction, mastectomy and simple augmentation. Thus we cannot use level I or II evidence. Adding the filter ‘case report’ (Level III evidence) produced a total of 61 results of which only seven were concerned with mastopexy techniques and outcomes. For this reason, the level of evidence for this chapter was set at level IV to allow inclusion of the opinions of respected names in breast surgery.

EVIDENCE FOR MASTOPEXY PROCEDURES

Periareolar Mastopexy

As with all aesthetic surgical procedures there is a trade-off between the stigmata of surgery – that is, surgical scars - and optimising the aesthetic outcome. Mastopexy is a prime example of this and the periareolar mastopexy attempts to disguise the surgical incisions around the areolar at the expense of limiting surgical access and exposure to the breast. The periareolar mastopexy is ideally suited to women with mild to moderate ptosis who have adequate breast parenchymal tissue to support the redraped skin. The incision around the areola may be doughnut or crescent shaped and the procedure can include the use of a breast implant if the underlying breast tissue is of inadequate volume and requires augmentation.

The periareolar mastopexy can be skin only (‘concentric’) excision where a donut of skin is de-epithelialised around the nipple and the outer skin is sutured around the nipple using a non-absorbable suture before the edge of the nipple and the breast tissue is closed with a skin suture as described by Rees and Aston [12].

Critics of the original description for concentric mastopexy argue that the periareolar scars can become widened and the areola stretched, with the breast’s overall appearance being flattened. Other complications of the periareolar incision can arise from incorrect placement of the periareolar scar and Spear et al. [13] discuss a series of rules to minimise these complications (Figure 5).

Figure 5. Rules for periareolar mastopexy: 1) $D_{\text{outside}} \leq D_{\text{original}} + (D_{\text{original}} - D_{\text{inside}})$; 2) $D_{\text{outside}} \leq 2 \times D_{\text{inside}}$; 3) $D_{\text{final}} = \frac{1}{2} (D_{\text{outside}} + D_{\text{inside}})$. Data from Spear et al. [13].

Spear has presented the results of concentric mastopexy following his guidelines, showing that for the 31 patients he operated on (21 with simultaneous augmentation) all healed with minimal excessive scarring, although four required 'minor' periareolar scar revision; the conclusion was that concentric mastopexy was a safe procedure when using Spear's guidelines [13].

In 2001, Spear revisited his original description of the concentric mastopexy, commenting on the increased popularity of the technique and the benefit of using a non-absorbable purse string suture around the areola to counteract the tendency of the areola to dilate [14]. Spear also commented that in his experience if the nipple is to be elevated more than three or four centimetres, a periareolar mastopexy becomes more risky and in women with small nipple areola complex, the chance of developing a widened scar was also increased. On reviewing his original second rule - that D_{outside} should be no more $2 \times D_{\text{inside}}$ - Spear suggests that using a non-absorbable blocking periareolar suture allows this rule to be modified to $3 \times D_{\text{inside}}$, although this was not supported by a presentation of his results.

Alternatively, the Benelli mastopexy [15] addresses the skin and glandular tissue separately with a teardrop shaped skin excision and then an inverted T type gland resection through the periareolar incision.

A further alternative to skin only or Benelli type periareolar mastopexy is the use of a prosthetic Vicryl and Dacron mesh used as an internal bra to support the lower pole of the breast as described by Goes. Goes has published a seven-year experience of his technique [16] in 254 mastopexy patients in which he used a periareolar approach and overlapped de-

epithelialised skin with a synthetic mesh between the skin layers for extra support. Complications from Goes' technique are reported by the author as 1.5% seroma rate, 1% haematoma rate and a 4% loss of areolar sensitivity.

Crescentic Periareolar Mastopexy

Puckett [17] described a technique of crescent mastopexy and augmentation for use in women with ptosis where the nipple is at the inframammary fold – a position they termed 'grade 1½ ptosis'. In a case series of 26 patients with a follow up of six months to four years Puckett commented that 'the lift appeared to be sustained over this period'. However twelve of the 26 patients had scar widening of five millimetres or more and five were left with oval areolas.

Short Scar Periareolar Inferior Pedicle Reduction (SPAIR) Mastopexy

Hammond [18] described a mastopexy technique based on his method of breast reduction using an inferior pedicle for the nipple and a circumvertical skin excision to address any excess skin. The proposed benefit of this technique is that it allows direct control of the volume of upper pole of the breast (termed 'auto-augmentation'), which is often deficient in patients requesting mastopexy. The inferior pedicle and the periareolar incision allow access to the pectoralis fascia to which the pedicle is sutured, thereby 'fixing' and uplifting the breast. Hammond describes this technique in 474 patients of which eight were mastopexy only, the remainder being breast reduction patients.

Vertical Scar Mastopexy

This technique is suitable for women with moderate to severe ptosis and poor skin quality who require some breast tissue to be excised to achieve an acceptable cosmetic result. The payoff is greater, more visible scarring compared to the periareolar technique, but in our opinion a more satisfactory 'fixing' of the breast can be achieved in these women who present with a greater degree of ptosis.

One of the original proponents of the vertical scar technique was Lassus [19] who described a technique that involves breast reduction with excision of glandular tissue, areolar transposition and no skin undermining, performed through an incision that closes with a vertical scar. In our experience, this technique is generally agreed to be most suitable for young women with firm glandular tissue, moderate ptosis and a skin envelope of decent quality. In 1996 Claude Lassus [20] reviewed his personal series of 710 patients, 1350 breasts operated on of which mastopexy was performed in 439 breasts using a vertical scar technique. In this series, two patients had total and eleven had partial nipple loss. In his review paper, Lassus comments that surgeons should use a lateral pedicle if moving the nipple more than nine centimetres, otherwise using a superior pedicle. He reports four cases of 'terrible hypertrophic scars' and sixteen 'severe' scars. Critics of the Lassus technique argue that

patients are left with an unacceptable bunching of the skin along the vertical scar that will take several months to settle down and some women are unable to accept this.

Moving forward from the Lassus technique, Lejour [21] modified the vertical scar technique to include undermining of the skin envelope, overcorrection of the breast deformity to account for later recurrence of ptosis and liposuction as necessary to further reduce the breast volume (Figures 6 and 7). Lejour has published large series of her results [22] showing the technique can be used for large volume breast reduction as well as mastopexy procedures. As with the Lassus technique, there is significant skin excess in the vertical scar that is accounted for by wrinkling the scar and by allowing time for the wrinkling to settle.

Figure 6. Markings for Lejour mastopexy. Adapted from Lejour M. 'Vertical mammaplasty and liposuction of the breast' [22].

Figure 7. Right-sided Lejour style mastopexy for breast asymmetry with left sided expander implant.

In 1999 Madeline Lejour published results from her own series of 250 consecutive patients (476 breasts) [23, 24] in which she stated she used the vertical scar mastopexy technique for every case except for women whose breasts were very small, who were undergoing augmentation mastopexy procedures and for those with tuberous breasts, in whom she used a periareolar approach. Complications of the Lejour technique reported by the author from the 476 operated breasts were two cases of partial nipple necrosis, a 5% seroma rate and a 1.2% haematoma rate.

L –Shaped Scar Mastopexy

Chiari [25] has described a further modification of the vertical scar technique by adding a single sided lateral horizontal component to the scar resulting in an L or J shaped scar. This technique was described for patients with moderate breast ptosis mainly due to skin excess but otherwise with a reasonable amount of breast tissue. Chiari advocates this technique over the standard vertical scar/inverted T techniques as the improved cosmetic results are immediately evident rather than having to wait three months, the breast retains projection, the areolar remains undistorted and is said to be less flattened in the inferior pole.

In 2012, Chiari published a prospective study of 125 breasts looking at breast sensitivity before and after L scar mammaplasty [26]. Breast sensitivity was tested using the Semmes-Weinstein esthesiometer preoperatively and six and twelve months postoperatively. Of the 125 breasts tested, 62 had tissue resection less than 200g and could be considered a mastopexy rather than formal breast reduction. In Chiari's study, using the L shaped scar, there was a return to preoperative sensation of the skin, areola and nipple by six to twelve months postoperatively in all cases where the resection weight was less than 200g.

Vertical Scar with Short Horizontal Component

Daniel Marchac (1982) described an adaption of the vertical scar technique mastopexy whereby he added a short horizontal component to excise excess skin and minimise wrinkling of the vertical scar seen with the Lassus/Lejour techniques [27]. This technique is most suited to women with a reasonable quality skin envelope requiring resection of a moderate amount of breast tissue to achieve a pleasing cosmetic outcome. Proponents of Marchac's technique argue that the vertical scar is the most visible breast scar whereas the horizontal scar is the least visible. Adding a short horizontal component is therefore a small price to pay for an immediately superior cosmetic result compared with the patience required following other vertical scar techniques.

Inverted-T (Wise Pattern)

This technique as described by Wise in 1956 [28] is commonly performed for breast reduction but is equally suitable for mastopexy procedures in patients with moderate to severe ptosis requiring minimal glandular resection and excision of a large amount of skin. Advantages of this technique are that the surgeon is most often familiar with the markings,

has good control over the amount of skin/breast tissue resected and can shape the breast so the result is immediately visible. Again the pay off for this type of procedure is that the scarring is greater than with periareolar or vertical scar techniques, but it is our view that for certain patients with significant ptosis this is a sensible approach if a large amount of skin resection is required.

Augmentation Mastopexy

Commonly women requesting augmentation post childbirth may require both lifting of the breast through a mastopexy procedure and augmentation of the breast as they feel they have lost breast volume. The mastopexy augment is therefore an attractive option, as the implant will fill out a previously stretched skin envelope. However this benefit must be weighed against the risks of wound breakdown due to increased tension on suture lines from the implant and potential of over resection of skin flaps during the mastopexy. Augmentation mastopexy leaves the surgeon the choice of any mastopexy procedure (except liposuction alone) as they all allow access to the chest for placement of the breast implant, and the choice of procedure should be tailored to the individual patient.

Calobrace [29] retrospectively reviewed his own five-year series 332 patients who underwent simultaneous augmentation mastopexy. The approach used by Calobrace varied depending on the degree of ptosis, and he employed periareolar (twenty percent), short scar (forty percent) and Wise pattern (forty percent) skin incisions as the degree of ptosis increased. Follow up ranged from one to six years with a mean of 1.5 years. Of the 332 patients operated on, 77 required reoperation, the most common indications being capsular contracture (11/332), poor scarring (11/332) and recurrent ptosis (11/332). There was no correlation between reoperation rate and the mastopexy approach used. Calobrace further comments that a poor cosmetic result was seen in 23.2% of augmentation mastopexy patients. When considering Calobrace's results, it should be remembered that there are many reasons patients may undergo repeat operations or indeed may choose not to have an operation even if it is indicated. Reoperation rate as an outcome measure is subjected to bias from many factors including patient psychology, surgeon preferences, economics, patient demographics – e.g. employment/childcare issues, fitness for further surgery, all of which can influence whether a patient proceeds to reoperation. As such it may not be sensitive indicator of patient satisfaction or dissatisfaction with surgery.

Scott Spear [30] has published results from his series of 53 bilateral and seven unilateral mastopexy augment patients with mean follow up of twelve months, in which he used both periareolar and vertical scar approaches. In his paper Spear states that primary simultaneous augmentation mastopexy has an early revision rate of eight percent and a complication rate of seventeen percent with many patients commenting postoperatively that they still desired a greater degree of lift. These findings can be placed in context when comparing results from primary breast augmentation, which is associated with a 1.7% revision rate.

Others have published their retrospective case series of augmentation mastopexy, including Cannon and Lindsey [31] who reviewed their results of 100 consecutive augmentation mastopexies performed via the periareolar approach only. Operated patients had either grade two ptosis (76%), grade three ptosis (16%) or tuberous breasts (8%) and follow-up averaged 8.3 months. In this series of periareolar mastopexies the overall

complication rate was eleven percent. There were three instances of moderate hypertrophic scarring, six of mild hypertrophic scarring and one partial nipple necrosis, the latter occurring in a patient with grade three ptosis requiring a seven-centimetre nipple lift.

Based on this experience, Cannon and Lindsey [31] have defined favourable patient factors they consider important for success in periareolar mastopexy:

1. Flaccid empty breasts
2. Small to moderate implant size (<360mls)
3. Planned nipple elevation of 4cm or less
4. Lighter skin tones
5. Absence of stretch marks

Stevens et al. [32] published their retrospective review of 321 consecutive single stage augmentation mastopexies in 617 individual breasts with an average follow up of forty months using inverted T (60%), periareolar (21%), vertical (15%) and crescent (4%) scars. The surgical revision rate was 14.6%, most often for implant related issues. The highest overall revision rate was in patients who underwent a periareolar mastopexy (it would be worth going into this in more detail – e.g. relative reoperation rates of periareolar versus other augmentation mastopexies, perhaps in the form of a table). As a comparison, Stevens et al. reviewed their own series of 150 mastopexy only patients and found this group had an 8.6% revision rate, which was twice the tissue related revision rate in their mastopexy-augment group. These mastopexy-augment figures can be compared to a large prospective study published by the breast implant manufacturer Mentor looking at augmentation-only patients (as opposed to augmentation mastopexy patients), which showed a reoperation rate of 13.2% at three years and 20% at five years [33].

Rod Rohrich [34] surveyed 1500 US Board-Certified plastic surgeons, receiving 487 replies (a 32.5% response rate). Questions included the surgeon's choice of mastopexy technique, their own satisfaction with their results, patient satisfaction and mastopexy complication rates. The most popular technique was inverted T (45.8%) followed by the SPAIR technique (32.6%) and then periareolar (30.6%); interestingly 71% of respondents used only one technique. Physicians were also asked to report patient satisfaction with the results of their surgery on a scale from one (unsatisfied) to five (very satisfied). Half of respondents reported patients rated their surgery at 4/5 and 40.9% at 5/5.

Most respondents reported a less than five percent complication rate, the most commonly (across all types of mastopexy) being suture spitting, poor scarring and bottoming out. Comparing types of mastopexy, the inverted T group had significantly greater incidence of bottoming out and the periareolar group had a significantly greater need for revision compared to other groups. Clearly there is significant potential for reporting bias in questionnaire surveys, in particular when asking surgeons to report recalled patient satisfaction with their surgery and the complication rate of five percent is much lower than that reported in other large mastopexy series discussed above.

Swanson [35] published a photometric study in which he analysed frontal and lateral images of pre- and postoperative mastopexy patients from 82 international publications on mastopexy and breast reduction. Swanson grouped the publications and photographs presented in them according to the mastopexy technique used.

Using simple measurements including upper pole, lower pole and total breast area, Swanson found that none of the techniques actually improved breast projection and, with the exception of the vertical technique, breast projection was actually reduced after mastopexy. Further, Swanson states that based on his analysis of photographs of mastopexy patients, no mastopexy technique produced a significant increase in upper pole projection and the use of fascial sutures did not have any lasting effect on upper pole fullness. The 82 papers examined included mastopexies carried out using inverted T, superior or medial pedicle, inverted T central pedicle, inverted T inferior pedicle, vertical scar, periareolar and intramammary approaches. Commenting on areolar shape, Swanson found that in 84.2% of all mastopexy studies, use of a Wise pattern or Lejour ‘mosque dome’ pattern resulted in an unappealing inverted teardrop areolar shape. This finding Swanson attributes in the Lejour markings to the creation of a dog ear superiorly when the vertical ellipse is closed and with Wise pattern markings being due to the unpredictable topography of the local skin around the new areolar. To maintain a circular areolar shape longterm, Swanson advocates using a closed technique whereby the areolar markings are not drawn preop but are marked later once the mastopexy has been completed, as advocated by Pitanguy [36].

CONCLUSION

This review of the evidence available for mastopexy procedures confirms the dearth of high-level evidence available for cosmetic surgery procedures, which means surgeons must rely on retrospective case series reviews and comments from respected sources. For a topic as large and complex as mastopexy there are good papers available including personal series of large numbers of patients with adequate follow-up. It is important to note that for younger surgeons beginning their careers they may not be able to match the results of more experienced surgeons as undoubtedly there are the numerous small steps included in mastopexy procedures by the ‘big names’ in breast surgery that are not commented on in these review papers and that contribute to the success of the described mastopexy procedures.

This chapter has covered the anatomy of the breast, as a clear comprehension of the blood and nerve supply to the breast is a prerequisite for performing a successful mastopexy procedure and for designing a safe pedicle for the nipple to be maintained on. The technique used to address skin excess is dependent on the degree of ptosis and the distance the nipple is to be elevated which in turn determines the eventual postoperative scarring. Of equal importance is the parenchymal distribution and breast volume preoperatively as the rearrangement of this tissue determines the eventual shape of the breast after mastopexy and influences the decision on whether to use an implant or not to augment the breast.

A striking finding on reviewing the available evidence is that there is no single mastopexy procedure that produces the desired long-term effect of a breast lift and adequate upper pole fullness. What is also clearly apparent is the high revision rate associated with all types of mastopexy procedure, which may well be a reflection of the complex nature of the problem and the high demands of this particular patient population.

Chapter 35

BREAST AUGMENTATION

Patrick Mallucci^{1,*} and Olivier Alexandre Branford^{2,#}

¹The Cadogan Clinic, London, UK and
Royal Free Hospital, London, UK

²Imperial College Healthcare NHS Trust, London, UK

KEY POINTS

- Breast augmentation must be seen as a process in order to achieve optimal results with a low complication rate and reoperative requirement
- The goals of breast augmentation are: to enhance the breast, producing a result that is pleasing and in proportion with the individual; to minimise distortion through careful implant selection; to avoid complications through good technique; and to achieve results with longevity
- Comprehensive patient education is key, providing them with the knowledge to make sound decisions about their breast augmentation
- Tissue based preoperative planning is a crucial part of the process of breast augmentation
- An understanding of the importance of aesthetic goals is crucial to achieving consistently attractive results and satisfied patients

BACKGROUND

Breast augmentation is currently the most frequently performed cosmetic surgical procedure, a position held since 2006, with the figures for 2013 being up one percent on the previous year [1]. Breast augmentation has traditionally been seen as an isolated simple surgical procedure. Evidence has shown that this philosophy is outdated and leads to poor

Corresponding Author's Email: olivier.branford@totalise.co.uk.

results, excessive complications and unhappy patients, requiring repeated postoperative consultations and resulting in reoperation rates of around twenty percent at three years, as shown in successive premarket approval studies [2, 3]. In this chapter we delineate an evidence-based systematic approach to consistently achieving the best possible results in breast augmentation, with the lowest possible complication rate and reoperative requirement.

This chapter deals with breast augmentation using breast implants since the safety of widespread use of injectables remains controversial. A brief review of fat transfer is included at the end of the chapter examining the latest evidence for its use in breast augmentation.

LITERATURE SEARCH

For the purposes of this chapter a comprehensive analysis of relevant evidence-based studies related to breast augmentation was made. The source for these articles was MEDLINE. We have emphasised evidence-based guidelines and primary research studies, rather than other review articles, unless they were systematic reviews, where possible. However due to the paucity of high level evidence related to some areas of the decision making process in aesthetic surgery we have also acknowledged lower level studies, controversies, recent developments, other viewpoints, and any apparent conflicts of interest or instances of bias that might affect the strength of the evidence presented where appropriate. Only 2.2% of articles have been shown to be level I evidence in plastic surgery [4]. This may be in part due to the inherent difficulties in surgery in performing randomised blinded trials. Individual case series, case reports, and expert opinion (levels III through V) can address some subtleties of surgical technique that are valuable to the practicing surgeon but not currently amenable to prospective, controlled, randomised trials⁵. Where appropriate these have been critically appraised and the level of evidence for key clinical recommendations indicated using the American Society of Plastic Surgeons (ASPS) Levels of Evidence Rating Scale for Therapeutic Studies (Appendix) [5].

Based on our findings we have provided an evidence-based step-wise process-based approach to the management of breast augmentation patients.

THE PROCESS OF BREAST AUGMENTATION

Definition

A process may be defined as a “Group of practices that are completed successfully to reach a goal” [6]. Adams and Mallucci have produced a comprehensive overview of breast augmentation and have recognised the importance of the process in achieving optimal results. [7] Adams has conducted a level II prospective cohort study in 300 breast augmentation patients to examine outcome following introduction of a comprehensive and defined process with a mean follow up of 2.1 years and overall reoperation rate of only 3.7 % [6]. In addition Adams analyzed two subcohorts within his study: saline and form-stable gel implants, comparing the process between these two groups, although he supplied no statistics in this part of the assessment. The respective reoperation rates were 4.7% and 2.9% for the saline

and form-stable implants. Adams [2, 3] validated his process for breast augmentation by comparing his data to Mentor and Inamed clinical trials data: when breast augmentation is seen as an isolated procedure there is a 15-24% reoperation rate.

Goals of the Process

Adams and Mallucci have clearly set out the goals for the process of breast augmentation [7]:

- To enhance the breast, producing a result that is pleasing and in proportion with the individual
- To minimise distortion through careful implant selection
- To avoid complications through good technique
- To achieve results with longevity

Tebbetts has succinctly stated in *primary* breast augmentation, the tissue environment and the decision processes by patient and surgeon are very different compared with breast reconstruction: in reconstruction, tissues are, by definition, already compromised or destroyed; a primary objective in primary augmentation is to avoid tissue compromise, reoperation, and deformities resulting from a primary, medically unnecessary operation [8].

In this chapter we will set out how to achieve these goals by respecting the natural proportions of the breast.

Primary Subprocesses

Adams and Mallucci have cited four primary goals for patient care in a recent CME article [7]:

1. Comprehensive Patient Education

The authors recommend that this should be performed by a patient education specialist prior to surgical consultation that enhances subsequent informed consent.

The principles of implant selection should be explained.

All attempts to ensure that patients have realistic expectations should be made.

Patients should be told that there is preoperative and postoperative asymmetry in 100% of patients [6].

Patients should understand the limitations of the procedure.

Patients should be provided with the knowledge for them to make sound decisions about their breast augmentation.

Rohrich and colleagues have published a retrospective study of 100 randomly selected patients assessed for nipple, breast mound and chest wall asymmetries by four independent physicians using standardised preoperative photographs [9]. They found significant asymmetries in all parameters, with nipple-areola complex position asymmetry in 53%, nipple-areola size asymmetry in 24%, mound asymmetry in 44%, inframammary fold position asymmetry in thirty percent and chest wall asymmetry in nine percent. Overall 88% of women exhibited some asymmetry, with 65% having more than one parameter of

asymmetry. The results of the study support the patient education recommendations by Adams and Mallucci with respects to preoperative counselling in terms of asymmetry.

2. Tissue-Based Preoperative Planning Evaluation

This is a crucial part of the process and is based on work by Tebbetts and Adams [6, 10, 11]. The basis of this approach is to use quantitative, objective data to enable objective rather than subjective decisions to be made with respect to preoperative planning. A number of systems have been described. In Europe Allergan has devised a computerised Biodynamic system: measurements are entered by the surgeon and the software computes a best fit implant. The drawback of this technique is that it uses external sizers tried on by patient, making it subjective. In the US Tebbetts and Adams have classified available tissue-based assessment systems into three generations as shown in Table 1 [12].

Table 1. US tissue-based assessment systems

Generation	Details of System
First	BioDimensional System (Inamed Corp.) Choosing an implant that forced tissues to match it
Second [11]	TEPID system: characteristics of breast Tissue, Envelope, Parenchyma, Implant, and implant Dynamics Defined measurements to match the implant to the patient's tissue characteristics and breast dimensions, instead of forcing tissues to a desired result
Third [12]	Key decision parameters and data from more than 2300 primary breast augmentations planned using the TEPID system were analyzed to define the five most critical decisions that affect reoperation rates and risks of uncorrectable deformities Uses 5 critical decisions to define a decision support process using five critical measurements

Tebbetts and Adams examined 1664 cases of breast augmentation planned using the TEPID system with up to seven years follow-up (although mean follow-up was not stated) in a level IV case series [12]. The overall reoperation rate was three percent, and reoperation rate for implant size exchange was 0.2 %. The junior author's (Adams) clinical experience included more than 300 augmentations with up to six years of follow-up using this system, with an overall reoperation rate of 2.8 %, relative to reoperation rates of seventeen percent rates in data from Mentor and McGhan which were submitted for their saline premarket approval studies in 2000 [13, 14]. As a result of this study the authors described five critical decisions in breast augmentation, which are shown in Table 2. The article provides a good system for implant choice, is quantifiable and had good numbers included in the study with good outcomes. The authors recommend their third generation published tissue-based system as the only one that uses measurements to determine optimal fill volume and an implant that fits the breast. In this part of the process observed dimensions are more important than volume, and these guide appropriate choice of implant. In this way it is possible to identify 'best fit' for the breast template causing as little distortion to the breast as possible, resulting in optimal fill while respecting natural boundaries.

3. Refined Surgical Technique

The surgical plan should be developed preoperatively following the surgeon's consultation. The authors recommend creating implant pockets under direct vision using careful prospective haemostasis techniques with no blunt dissection to minimise tissue trauma and ensure a rapid recovery [7, 15, 16].

Table 2. The five critical decisions in tissue-based preoperative planning

Decision	Measurement/ Comments
Implant plane	Determines soft-tissue coverage Determined by soft tissue pinch thickness
Implant volume	This is based on predicted tissue-based optimal fill volume of the breast: this is determined by breast base width with adjustments for skin stretch, and minor adjustments for nipple to inframammary fold distance and for estimates of parenchyma to stretched envelope fill (although this last parameter appears difficult to achieve in a fully quantitative way)
Implant type, size and dimensions	Based on discussion between patient and surgeon Base width of the implant selected should not exceed the base width of the patient's existing breast For ptotic breasts it is advisable to favor higher profile anatomical implants to inflate lower pole Where skin is poor and there is little parenchyma lower profile anatomical implants are the best choice
Optimal location of IMF	If the recommended intraoperative nipple to inframammary fold distance for the planned volume implant is greater than the patient's preoperative nipple to inframammary fold distance under maximal stretch, the surgeon should consider lowering the fold to the recommended level If the recommended nipple to inframammary fold distance is the same or longer than the patient's preoperative nipple to inframammary fold distance under maximal stretch, no lowering of the fold is indicated
Incision site	Based on patient preference and surgeons preference and skill set Inframammary, axillary, periareolar or umbilical

4. Strictly Defined Postoperative Plan

All patients should be given detailed defined postoperative instructions with respect to wound care, avoiding underwired bras, the need to keep mobile and when to commence light aerobic activity and more strenuous exercise.

BREAST AESTHETICS

When planning breast augmentation it is essential to have an aesthetic goal. Penn described a triangle of aesthetic proportion in relation to breast reduction [17]. However, it would be possible to have Penn dimensions and an unattractive breast due to the article lacking important definitions of proportion. Other authors have tried to recommend various proportions to define ideal breast proportions but have used random populations of women not chosen for the attractiveness of their breasts and made no attempts to define attractiveness [18].

We have recently identified four key parameters that may be using to assess good results in breast augmentation and as a guide in the design of aesthetic breast surgery [19]. In a quantitative observational study of 100 topless models chosen by the editors of mass print media for the attractiveness of their breasts, we identified specific proportions that were common to all of them (Figure 1, Table 3).

Figure 1. Three quarter profile view with standard breast parameters: U:L proportion, nipple angulation, contour of upper and lower poles. These images show three different breast sizes: all 3 models have a U:L ratio of 45:55, straight or concave upper poles, 20° upward angle of nipple pointing, and convex lower poles. U = Upper pole, L = Lower pole, UPL = Upper Pole Line, LPL = Lower Pole Line, nm = Nipple Meridian, UPS = Upper Pole Slope, LPC = Lower Pole Convexity, a = nipple angulation. [19]

Table 3. Results of analysis of breasts for four key features in 100 models [19]

Parameter	Result (n = 100)
Vertical Height of Upper Pole: Vertical Height of Lower Pole	45:55
Nipple Pointing from Horizontal	20° upwards
Upper Pole Contour (%) Concave: Straight: Convex	61:33:6
Lower Pole Convexity	Smooth convex curve in 100%

Our analysis revealed that the lower pole of the breasts was invariably fuller than the upper pole. The nipple meridian lay at a point such that on average the proportion of breast above it was 45% and below it 55%: the so called 45:55 ratio. In the vast majority of breasts the upper pole was either straight or concave (61% and 33% of cases respectively). The upper pole was convex in only six percent of cases. The angulation of the nipple was upwards from the horizontal at a mean angle of twenty degrees. In all cases the breasts demonstrated a tight convex lower pole. No ptotic breasts were seen. The results of our study may be used to guide implant selection, incision placement and pocket dissection in breast augmentation, to achieve consistently attractive aesthetic proportions. The aesthetic vocabulary generated by this study may also be used, for the first time, to quantitatively assess good and bad results in aesthetic surgery.

The importance of nipple position in determining breast attractiveness has also been suggested by other authors, although they did not define what the ideal nipple position should be, and they did not define attractiveness as the study examined just ten patients out of a random selection of volunteers [20].

PREOPERATIVE ASSESSMENT

It is extremely important to identify, record and point out asymmetries to patients preoperatively. Structural asymmetries should be noted, including pectus excavatum/ pectus carinatum, sternal rotation, scoliosis and thoracic hypoplasia, which is the most common abnormality. The lie of the breast on chest wall should be recorded, especially lateralisation of the nipple and breast, as the postoperative intermammary distance is determined by the preoperative state.

The minimum recommended preoperative measurements are shown in Table 4.

It is also useful to make an assessment of parenchymal fill as percentage of volume of skin envelope, although this is difficult to do in a quantitative way.

The most important of these parameters in determining implant selection is breast width, with skin stretch of envelope being the next most important factor¹². The other dimensions will further guide the selection process but to a lesser extent. Chest wall shape and anomalies will determine implant height and projection.

Table 4. Recommended preoperative breast measurements in breast augmentation

Measurements	Comments
Soft-tissue pinch thickness:	Pinch with index and thumb and measure using other hand using calipers
Of upper pole	If <2cm then choose dual plane or partial retropectoral [15]
Of lower pole (at inframammary fold)	If <0.5 cm, surgeon preserves intact pectoralis muscle origins along IMF for additional coverage, creating a partial retropectoral pocket (compared with a dual-plane pocket) [15]
Breast base width	Using calipers From parasternal origin of pectoralis major to lateral aspect of breast
Degree of skin stretch	Done by measuring the forward displacement of areolar skin during maximal pull Care must be taken not to cause discomfort
Nipple to sternal notch	
Breast height	
Nipple to inframammary fold distance	On maximum stretch
Intermammary distance	

CONSENT AND COMPLICATIONS

The complications that should be discussed preoperatively have been succinctly summarized by Adams and Mallucci (Table 5) [7]:

Table 5. Complications in breast augmentation

Complication
Bleeding/hematoma (1% risk)
Infection (should be 1% risk)
Use of drains
Seroma
Sensory changes to the nipple and or breast (common in the short term)
Scarring
Asymmetry
Implant visibility/palpability
Implant rippling
Malposition of the implant
Implant rupture (1-2% at 10 years)
Implant rotation (anatomical) (2%)
Soft-tissue stretch (stretch marks)
Glandular atrophy (over time)
Galactorrhea
Capsular contracture (5% for textured silicone)
Anaplastic large cell lymphoma (implant related) (see below)
Need for reoperation at some stage in the future (approximately 20% at 10 years)
Mammography plus breast cancer detection
Silicone controversy
Financial implications for the future

Anaplastic Large Cell Lymphoma

Jewell and colleagues have reviewed the current evidence relating to possible associations between breast implants and Anaplastic Large Cell Lymphoma (ALCL), a rare non-Hodgkin's lymphoma [21]. They found eighteen publications describing 27 cases of ALCL in breast implant recipients: 78% of cases had an indolent course. There is no prospective epidemiological study in the literature linking implants and ALCL although there are seven such studies that suggested that the observed non-Hodgkin's lymphoma cases were comparable to expected non-Hodgkin's lymphoma cases based on population rates.

In a Level III systematic review Kim and colleagues found that when ALCL does occur around breast implants it seems to develop in the capsule surrounding the breast implant and/or presents as an unexplained seroma or mass and may only require removal of the implant and capsulectomy, with clinical follow up. This may simply reflect a different pattern of breast cancer seen in breast implant patients rather than an increase in the condition. Ultimately, understanding the biology, treatment, and prognosis of implant-associated ALCL will require substantial research efforts, such as in vitro experiments using immortalised implant-associated ALCL cell lines, collection of detailed clinical information in breast implant registries, and well-designed epidemiologic studies [22]. ALCL remains a rare

association without evidence of causation, occurring at a frequency of one in one million women with and without breast implants [23].

In a more recent Level V article by Kim and colleagues conducted a structured expert consultation process consisting of a multidisciplinary panel of ten experts, selected based on nominations from national specialty societies, academic department heads, and recognised researchers in the United States [24]. The panellists agreed that:

There is a positive association between breast implants and ALCL development but likely under recognition of the true number of cases.

A recurrent, clinically evident seroma occurring six months or more after breast implantation should be aspirated and sent for cytologic analysis.

Anaplastic lymphoma kinase-negative ALCL that develops around breast implants is a clinically indolent disease with a favourable prognosis that is distinct from systemic anaplastic lymphoma kinase-negative ALCL.

Management should consist of removal of the involved implant and capsule, which is likely to prevent recurrence, and evaluation for other sites of disease.

Adjuvant radiation or chemotherapy should not be offered to women with capsule-confined disease.

Little agreement, however, was found regarding etiologic risk factors for implant-associated ALCL and further research is needed to improve our understanding of the epidemiology, clinical aspects, and biology of this disease.

CHOICE OF IMPLANT

Filler

Saline vs. Silicone

Saline implants exhibit several problems, such as palpability, underfilling, overfilling, deflation and they have a firmer consistency and unnatural feel, compared with silicone implants [25]. The saline vs silicone debate has a long history based more on a series of unfounded health scares and high profile media cases under the auspices of biased regulatory bodies than patient satisfaction with their implants. Anecdotal data and individual case reports of possible systemic symptoms that were associated with patients who had received silicone breast implants led to a reclassification of this type of implant by the FDA in 1988. This reclassification and the FDA requirement that manufacturers obtain premarket approval of the implant before making it available for widespread sales generated a public controversy in 1990 and 1991. The result of the controversy was a ban of the silicone gel implant for augmentation mammoplasty in the US and a restriction of its use to mastectomy reconstruction to patients who were enrolled in a restrictive trial protocol entitled the "Silicone Gel Adjunct Study". The moratorium on use of silicone implants lasted between 1992 and 2006.

Silicone implants have been approved for general use since the 2006 following Food and Drug Administration (FDA) clinical trials and panel hearings. Over 25 Level II and III scientific studies, some involving up to several hundred thousand subjects each, and over ten Level I meta-analyses (quantitative systematic reviews) show no link between breast

augmentation and autoimmune connective tissue disease [26]. Court-appointed national science panels [27] and the Institute of Medicine report entitled “Safety of Silicone Breast Implants” [28] also found no evidence that systemic disease is associated with breast implants. Despite this almost unequivocal evidence there is still some resistance from anti-implant groups, supported by repeated FDA scares often based on conjecture, anecdotal or individual case reports relating to different aspects of breast augmentation, prior to studies being developed to show that these are frequently unfounded concerns in the clinical setting. It is clear from the evidence that the burden of proof lies heavily with the profession and not with regulatory authorities, and may be related more to the FDAs fear of litigation than their scientific objectivity [29, 30].

There have been problems with junk science, sensationalist media, and legal battles based on lawyers playing on the emotion of juries rather than scientific method [31]. However, regardless of the level of regulation, the plastic surgical profession does need to play a role in auditing outcomes and contribute to research into new implants [32]. In this way problems such as have been seen with a higher than expected rupture rates associated with the use of poor quality implants such as the Poly Implant Prothèse (PIP) implants, with unauthorised industrial grade silicone as a filler material, manufacturing defects, shell thickness variation and inadequate quality control [33], will be detected more rapidly. It would be best for patients if regulatory bodies and governments work together with surgeons with the common goal of achieving consistent results with optimum safety

Silicone implants are used in Europe and the rest of world outside the United States due to their superior feel and durability. The silicone gel in these implants has been made to be progressively more cohesive by cross-linking of silicone. This gives the implants a firmer consistency, making them form-stable: the implants maintain their shape without collapsing and are resistant to deformation by the surrounding soft tissue envelope and capsular contracture. The gel in such implants does not extrude from the implant through violations of envelope integrity. However, due to these reasons of resistance to deformation, the use of form-stable implants requires an even more careful evaluation of the patient’s chest dimensions to determine the appropriate style of implant in order to avoid distortion [25].

Other Implant Fillers

Trilucent (soybean oil) implants have also been used and were vigorously marketed as having the advantages of a natural composition and radiographic translucency. These were withdrawn from use due to elevated carcinogen levels being detected in the breakdown product of soya Hydrogel implants. The Medical Devices Agency in 2000 recommended that all Trilucent breast implants should be removed from patients. The safety of the implants were questioned in two cases where Trilucent implants caused symptomatic local tissue reactions and capsule histology showed inflammatory changes [34]. Rizkalla and colleagues found in a Level IV case series that free oil was found around the implant in 34% of patients, concluding that the implants tended to bleed [35]. Kirkpatrick and Jones examined 51 explanted Trilucent implants and two factory-retained prostheses, and found that the soybean oil in all of these had undergone peroxidation, yielding potentially genotoxic aldehyde by-products [36]. The concentrations were 1000 times that thought to be potentially genotoxic. In a more recent multicentre study to assess the potential hazards from exposure to these lipid peroxidation products Williams and colleagues found although explanted Trilucent implant

soybean oil filler contained substantial levels of genotoxic lipid peroxidation products, particularly malondialdehyde, no progenitors of breast carcinoma were seen. Further, the location of the implants precluded these products from reaching the mammary epithelial cells which are progenitors of breast carcinoma [37]. The authors also found that blood levels of the peroxidation products were not elevated.

Hydrogel breast implants were withdrawn from use in the UK in 2000 due to concerns about the metabolic fate of the implant filler material, the hydrogels polyvinylpyrrolidone (PVP) and guar gum. In a retrospective audit of 66 women Hardwicke and colleagues reported that the implants also had double the implant rupture rate of saline-filled implants. The authors hypothesised that an osmotic gradient occurred due to the hydrogel filler causing the implants to swell and weaken the elastomer shell, leading to the observed implant rupture. A vigorous inflammatory tissue reaction was seen when PVP and guar gum filler were released into the subcutaneous tissues, causing pain and swelling [38].

As a result none of these implants using alternate implant fillers are in current use.

Surface Texturing

Smooth vs. Textured

Surface textured implants were designed to mimic the polyurethane implant rough porous surface and two percent capsular contracture rate [39]. Textured implants come at a cost of more visible rippling and greater palpability, as well as greater cost for the implants [25]. However, the most important difference between smooth and textured implants is with respect to the associated rates of capsular contracture. In an early retrospective level III study Ersek showed compared the rate and incidence of capsular contracture of smooth and textured silicone breast implants, showing that moderate to severe capsular contracture occurs in up to 45% of patients for smooth implants and five percent for textured implants [40].

Level I studies have not supported surface texture reducing capsular contracture in the subpectoral plane, although there may be benefit in the subglandular plane [41-43]. In a level I meta-analysis of seven randomised controlled trials Barnsley and colleagues found that only three of these studies found significantly reduced rates of capsular contracture with the use of textured implants [44]. However the authors found that when all seven studies were pooled there was a protective effect for surface texturing on the rate of capsular contracture with an odds ratio of 0.19. Again the authors found that there was no significant difference when comparing contracture rates between smooth and textured implants in the submuscular plane, although this subgroup was from a single study that was underpowered. These findings may be attributable to capsular contracture being more difficult to appreciate in the deeper submuscular plane or textured surface implants having no impact on capsular contracture when placed submuscularly. Similarly, in another level I systematic review, Wong and colleagues examined six randomised controlled trials and found that the relative risk of capsular contracture when comparing smooth and textured implants was four at one year, seven at three years and three at seven years [41].

Shape

Customization of implants by implant companies allows for different projections for a given volume. Published series indicate that moderate projection devices have the lowest reoperation rates and rates of uncorrectable deformities [11, 12, 15, 45]. Tebbetts has warned against the use of high- or extra-high-projection implants for primary breast augmentation and that a wide range of primary augmentation can be adequately treated with moderate projection devices [8].

Implants may be round or anatomical (also known as “tear-drop” or shaped implants). These latter are devices where the vertical axis is different in dimension than the horizontal axis [25]. Anatomic implants allow for even greater variability in implant selection allowing for choice of width, height and projection. For example, tall teardrop shapes are best suited for patients with a long chest or low breast position [25], and a “reduced height”-shaped device creates a relatively exaggerated width with abbreviated height to decrease upper-pole fullness [46].

There has been controversy as to whether anatomic implants are really anatomic and whether round implants behave anatomically *in vivo*. In a review article on breast augmentation Spear has stated that overall with an anatomically shaped implant there is a diminished tendency toward upper-pole bulges, roundness, or distortion and greater volume support for the lower breast, particularly in thin patients, those with a high inframammary crease, ptotic patients, and those with a vertically or horizontally deficient chest [25].

The indications for implant shape have been succinctly summarised by Adams and Mallucci [7]:

Round

- Fuller appearance
- Small volumes (less impact at small volumes)
- Good anatomy and skin quality
- Previous rotation
- Athletic individuals (rotation)
- Certain breast/chest wall shapes

Anatomical

- Desire for natural appearance (Figure 2 and Figure 3) and implant that ‘fits’ their breast
- Constricted lower pole
- Thoracic hypoplasia
- Breast reconstruction
- Mild ptosis or pseudoptosis

In addition in a recent study by Cárdenas-Camarena and Encinas-Brambila examining whether round or anatomical implants should be chosen the authors concluded that specific clinical features should determine implant selection [47].

Figure 2. Preoperative anteroposterior view and three quarter views of patient requesting breast augmentation.

Figure 3. Postoperative anteroposterior view and three quarter views of patient from Figure 2 post symmetrical anatomical breast augmentation demonstrating an attractive natural appearance with upward pointing nipples, a slight concavity to the upper pole and a full convex lower pole as described in our recent study [19].

They suggested that anatomical implants should be used for patients with significant differences in chest height and width measurements, for cases of significant mammary asymmetry, for patients with a small breast volume, and for breasts with a significant deficit of inferior mammary volume or significant shortening of the breast. The authors recommended round implants for patients with a superior pole deficit or moderate breast pseudoptosis, for patients with a breast that will cover the implant, and for patients with a small asymmetry.

It would follow that for patients with breast asymmetry where one breast fits into the first clinical category and the other into the second that these patients should be treated with an anatomical implant on one side and a round implant on the other. We have reported a case of

breast asymmetry where the principles of biodimensional implant selection have been used resulting in selection of a round implant on one side and an anatomical implant on the other side in the same patient [48]. To our knowledge, prior to our case, a round implant and an anatomical implant have not been previously employed in the same patient to correct asymmetry. We simply chose the best fit based on breast and chest wall dimensions, choosing asymmetric (different volume) asymmetric (different shaped) implants. The same biodimensional approach should be applied to both round and anatomical implants. Surgeons should have the confidence in being able to step between the two implant shapes based on dimension rather than compartmentalizing them away from each other: In this case we have crossed the boundary between anatomical and round implant selection.

Generations of Breast Implants

Cronin and Gerow were the first to use a silicone prosthesis for breast augmentation in 1961 [49], replacing the antecedent, less well tolerated practice of injecting silicone directly into breasts targeted for augmentation. There has been an evolution in every aspect of the devices (Table 6).

Table 6. Generations of breast implants [7]

Implant Generation	Production Period	Characteristics
First	1960s	Thick shell (0.25-mm average); thick, viscous gel; Dacron patch
Second	1970s	Thin shell (0.13-mm average); less viscous gel; no patch
Third	1980s	Thick, silica-reinforced, barrier coat shells
Fourth	1992–present	Stricter manufacturing standards; refined third-generation devices
Fifth	1993–present	Cohesive silicone gel–filled devices; form-stable devices

The current breast implants are fifth generation: the Style 410 implant being the first of the fifth-generation implants, distinguished by its highly cohesive, form-stable, silicone gel filler. The extent of cross linking of the silicone polymers during the manufacturing process is what determines the firmness of the silicone gel. As mentioned previously, when the filler crosslinking occurs to the degree that the silicone gel breast implant will maintain its dimensions and form (i.e., gel distribution within the shell) in any position, the cohesive gel implant is said to be form-stable [50]. In a Level II prospective, multicentre, non-randomised Investigational Device Exemption study with three-year follow-up data Bengtson and colleagues examined clinical outcomes and patient satisfaction in 941 patients undergoing highly cohesive anatomical silicone breast implantation (492 subjects underwent primary breast augmentation) and found that the Allergan Style 410 has low complication rates and high satisfaction rates. [51] Implant malposition was the most common complication (2.6%) and all other complications occurred in less than two percent of augmentation subjects, with Baker grade III and IV capsular contracture in 1.9%, and implant rupture occurring in 0.7%.

The risk of reoperation, another key safety endpoint, was 12.5%, with the primary reason being implant malposition. More than half of patients having their implants removed did so to change the size or style. This study reaffirms the safety of modern implants, and highlights the importance of careful preoperative planning in order to reduce reoperation rates. Hedén reported similar results in an earlier study of 1676 implants, the largest series in the world, using the Inamed Style 410 Matrix implant system, with four percent capsular contracture, less than one percent rotation, and less than one percent device rupture [52]. Not all form-stable implants are equal: in a Level II prospective cohort study comparing highly cohesive, form-stable breast implants Jewell and Jewell showed that rippling was significantly lower for the Allergan Natrelle 410 implant relative to the Mentor Contour Profile Gel, with rates of 7.6% and 37.3% respectively [53].

PREOPERATIVE MARKING

Preoperative markings are shown in Figure 4 in a patient with significant chest wall and breast asymmetry. Anteroposterior preoperative (Figure 5) and postoperative (Figure 6) photographs of the same patient are also shown.

Mark midline, inframammary folds (IMFs) and orientation marks (medial line on areola).

Once the implant dimension and nipple to IMF distance are known the surgeon can decide on the location of the inframammary incision – if the nipple to IMF distance is shorter than the implant dimension the incision will be below IMF so that it will lie in the IMF postoperatively.

Mark a 4-4.5cm incision commencing 1cm medial to areola going laterally.

Mark medial and lateral width of pocket using callipers to delineate this on the skin.

Mark height of pocket based on implant height going up from level of incision.

Figure 4. Preoperative skin markings in a patient with significant chest wall and breast asymmetry showing midline, inframammary fold, pocket size and incision markings.

Figure 5. Preoperative anteroposterior view of patient marked in Figure 2 showing significant asymmetry.

Figure 6. Postoperative anteroposterior view of patient marked in Figure 2 following asymmetric anatomical implant insertion.

INCISION PLACEMENT

Choices for incisions in breast augmentation are inframammary, periareolar, transaxillary, and transumbilical. In addition, an endoscope may be used for assistance [54]. In general, the inframammary and periareolar approaches will provide improved access as compared with the axillary or transumbilical approaches [25, 55]. However, there are other factors that may certainly influence the choice of incision. A very thin Asian patient without significant breast tissue, lacking a defined inframammary fold, may be at risk for increased prominence of an inframammary scar. An extremely small areola may limit the access

potential through this approach in these patients. Such factors should be taken into account when considering incision choices [56]. Adams and Mallucci have succinctly summarised the advantages and disadvantages of the various different incisions as shown in Table 7 [7].

Table 7. Advantages and disadvantages of incisions [7]

Incision	Advantages	Disadvantages
Inframammary	Most control Ability to manipulate/set inframammary fold Least implant effects (trauma and contamination)	Scar not ideal unless planned properly
Periareolar	Good access to breast Scar can be very well disguised usually	Can result in poor scarring; higher capsular contracture rates Contamination theory Nipple-areola complex sensitivity more affected Remote from pocket; tends to promote blunt dissection
Transaxillary	No scar on breast	Less controlled pectoralis major release unless endoscopically assisted Dual-plane dissection not possible

THE IMPLANT POCKET

Pocket Choice

Implant placement may be subglandular, subpectoral, total submuscular, or “dual plane”. Tebbetts has summarised the tradeoffs and potential benefits of each pocket type, as shown in Table 8 [15]. The patient’s breast habitus, including shape and tissue characteristics, should also be considered when making this choice. In a level III retrospective comparative analysis Biggs and Yarish shown that submuscular placements, whether partial or total, have a lower capsular contracture rate than subglandular placements [57].

In addition, the subglandular position places the implant closer to the skin surface, thereby increasing the potential for palpable or visual irregularities, particularly in patients with a paucity of breast tissue. The submuscular (or subpectoral) plane is preferable in achieving accurate mammography [58].

Currently, the total submuscular position for implant placement in breast augmentation is used infrequently. It requires a suberratus anterior dissection for a portion of the pocket development, which is an unnatural plane. Other potential disadvantages are disruption of the inframammary fold and a distortion of lower pole shape [56].

Table 8. Choice of pocket

Pocket	Tradeoffs	Potential Benefits
Subglandular/ Retromammary (when pinch test >2- 3 cm)	• Increased risk of edge visibility or palpability. • Possible increased interference with mammography. • Possible increased incidence of capsular contracture.	• Increased control of breast shape. • Usually a more rapid postoperative recovery. • Minimal or no distortion with pectoralis contraction. • Increased control of inframammary fold position and shape.
Partial retropectoral (without dividing pectoralis origins along the inframammary fold)	• Lateral implant displacement over time, widening the space between the breasts. • Less control of upper medial fill. • More postoperative tenderness and a more prolonged recovery. • Distortion of breast shape with pectoralis contraction. • Less precise control of inframammary fold position, depth, and configuration. This potential tradeoff is minimised or eliminated by division of pectoralis origins along the inframammary fold in patients who have adequate soft-tissue coverage. • Increased risk of superior implant malposition or displacement (when inferior pectoralis origins across inframammary fold are not divided). • Longer time required for deepening of the inframammary fold (when pectoralis origins along the inframammary fold are not divided)	• Muscle coverage mandatory if pinch thickness <2cm above breast parenchyma. • Possibly more accurate mammograms. • Less risk of palpable or visible implant edges. • Possible decreased risk of capsular contracture (small difference with saline-filled implants, greater difference with silicone gel-filled implants).
Total submuscular	• All tradeoffs listed above for partial retropectoral, plus: • Highest risk of superior implant displacement or malposition. • Longer operative time. • Longest postoperative recovery and morbidity. • Least accurate and predictable inframammary fold and longest to achieve depth. • Greatest risk of inframammary fold irregularities, lateral flattening, and fold level inaccuracies.	• Possible increased coverage inferolaterally but clinically no significant additional cover long-term.

Tebbetts has described a dual plane technique in a level II prospective comparative study [15]:

Definition: Implant lies partially behind the pectoralis major muscle *and partially behind the breast parenchyma.*

Totally divide specific origins of pectoralis major to reposition the muscle relative to implant.

Parenchyma-muscle interface is specifically altered to change implant-parenchymal dynamics. Parenchymal attachments to muscle are freed by dissecting in retromammary plane to different degrees depending on breast type as set out in Table 9.

Table 9. The Dual Plane technique [15]

Plane	Dissection
Dual plane I	Division of inferior pectoral origins only with no division of pectoral origin along the sternum
Dual plane II	Division of inferior origins with no division of pectoral origin along the sternum + release of anterior pectoral fascial attachments to gland with rotation upwards of inferior origin to level of inferior areolar border
Dual plane III	Division of inferior origins with no division of pectoral origin along the sternum + release of anterior pectoral fascial attachments to gland with rotation upwards of inferior origin to level of upper areolar border

The advantages of the dual plane technique as stated by Tebbetts are shown in Table 10. While good numbers were included in this study 468 patients (936 breasts), the distribution of patients to dual-plane type was not randomised but based on breast type. In addition the approach and implant type was not randomised but based on patient preference. Tebbetts did not say whether the results were graded by independent observers or the author, although patient satisfaction was assessed. No statistical or significance data was provided in this study.

Table 10. Advantages of dual plane technique [15]

Advantages
Good upper pole/medial cover
Improved draping of lower pole of breast over implant
Reduction in pectoralis animation
Lower capsular contracture rates [59]
Good mammographic visibility of the breast
Maximises benefits of retromammary and partial retropectoral approaches while minimizing tradeoffs
May be used in wide range of breast types
Adjusts implant-soft-tissue relationships to ensure adequate soft-tissue coverage while optimizing implant-soft-tissue dynamics
Adds options for treating breasts with highly mobile parenchyma, glandular ptotic breasts and constricted lower pole breasts

Pocket Dissection

This has been elegantly described by Tebbetts, Adams and Mallucci [7, 15]:

Start medially then sweep laterally.

Identify pectoralis major/pectoralis minor division in upper third of pocket and serratus anterior muscle.

Come medially superiorly again and divide and accessory medial pectoral origins, but not the main origin.

‘Prospective haemostasis’ and diathermy perforators before cutting them. Adams uses monopolar forceps to do the dissection.

Pocket Preparation and Irrigation

Burkhardt and colleagues conducted two prospective controlled blinded clinical studies on the use of a povidone-iodine containing solution irrigation of the pocket [60, 61]. In the first of these studies the authors failed to show a reduction in the risk of capsular contracture [60]. However in a later study Burkhardt and colleagues showed a significant reduction in class III-IV capsular contracture from saline-irrigated implant to implants irrigated with Betadine solution (27% vs. 10% respectively) [60, 61]. However, the results may have been influenced by the fact that more of the Betadine-irrigated devices were textured, which may have reduced capsular contracture rates, favourably distorting the results. Also, using the smooth, saline-irrigated implants as their standard the authors failed to show that the Betadine solution alone (or texturization alone) was able to significantly reduce capsular contracture rates, however when combined this did significantly improve outcomes as a cumulative effect.

Adams conducted a level IV prospective case series [62] demonstrating a low incidence of capsular contracture using triple antibiotic breast irrigation in 165 patients undergoing primary breast augmentation. They showed a Grade III/IV capsular contracture of 1.8% compared with 9% in other published reports [63-65]. However the authors changed their antibiotic regime half way through the study (from povidone-iodine/cefazolin/gentamicin to bacitracin/cefazolin/gentamicin) due to the U.S. Food and Drug Administration’s ban on povidone-iodine use during placement of breast prostheses (this ban was introduced despite the absence of any evidence that extraluminal povidone-iodine contributes to implant shell failure). The study had a mean follow-up of only fourteen months, although the authors noted that all contractures occurred within one year of surgery.

Pajkos and colleagues conducted a level II comparative prospective, blinded, clinical study of implants and capsules removed from patients with or without significant capsular contracture to investigate the association of biofilm contamination, breast implants, and capsular contracture [66]. They tested the capsule and implant samples by routine microbiological culture, sensitive broth culture and scanning electron microscopy. They found that routing swab cultures were negative in all samples. The sensitive broth culture samples were positive in seventeen of nineteen samples from patients with significant contractures, compared with only one out of eight samples obtained for patients with minimal or no contracture, a highly significant difference. Fourteen of the seventeen positive cultures from significantly contracted breasts yielded coagulase-negative staphylococci, mainly species of the *Staphylococcus epidermidis* group.

Taken together these reports add to the theory that the biofilm is implicated in the pathogenesis of contracture, and that steps should be taken to prevent its formation [66, 67].

POSTOPERATIVE MANAGEMENT

There is little evidence-based support for any specific postoperative recommendation, but general recommendations include mobilizing the patients early to reduce the incidence of complications and wearing a non-underwired supportive/sports bra six weeks postoperatively. Spear recommends the use of a support brassiere with a binder strip placed across the superior pole for ten to fourteen days to minimise the risk of rotation when using anatomic implants [25].

FAT TRANSFER AND BREAST AUGMENTATION

The use of fat injection to the breast as an alternative to the use of implants in breast augmentation remains controversial [68, 69]. Khouri and colleagues have advocated the use of a bra-like vacuum-based external tissue expander, the Brava device, prior to and following fat transfer, reporting highly significantly improved mean augmentation volumes (233ml versus 134ml) and graft survival (82% vs. 55%) in a level IV prospective multicentre study which was compared with a meta-analysis of six published reports [70].

Fat transfer for breast augmentation is being used increasingly and a large number of studies have appeared in the scientific literature, some with a large number of patients and with relatively long follow up for at least a proportion of those patients studied [68]. Delay and colleagues retrospectively examined their patients in a level IV study undergoing 880 procedures over ten years [71]. Breast reconstruction procedures accounted for 734 of these procedures and 30 were for aesthetic breast surgery. The authors found no increased risk of local recurrence of breast cancer or development of a new cancer in their first patients with ten-year oncological follow up. A number of studies appear to have settled the debate over whether breast augmentation with autologous fat leads to calcifications and cysts that might hinder mammographic examinations for the detection of breast cancer [68]. The postoperative radiologic appearance is usually that of normal breasts, sometimes showing images of fat necrosis that will not confuse the differential diagnosis of cancer for radiologists experienced in breast imaging [71]. Delay and colleagues acknowledged that for their study this finding was in a group of patients who had been treated by a surgical team that had completed its learning curve with modern approaches to fat transfer and with good communication with specialised radiologists familiar with the images produced by fat transfer. The authors advocated that in the context of fat injection for aesthetic surgery the principal radiologic risk is that a breast cancer may occur at the same time as lipomodelling. They recommended that in order to reduce this risk, imaging investigations (mammography and ultrasound) should be carried out before lipomodelling by a specialised radiologist in order to ascertain the absence of a suspicious lesion. The authors advocated that if there is any doubt, lipomodelling is deferred or contraindicated. The authors also advised a one-year postoperative radiological assessment. They felt that sufficient volume could be obtained for lipoaugmentation to be effective in patients requesting a natural appearance with a moderate increase in volume, with sufficient donor adiposity. Delay also advocated fat transfer as an adjunctive treatment for the imperfections and complications of implants.

In a recent level V prospective case series in twelve patients using pre- and postexplantation three-dimensional imaging Del Vecchio has shown that fat transfer may be used in combination with preexpansion of the breast subcutaneous tissue (the “third space”) to achieve comparable breast volumes in patients requesting removal of their implants in a single stage [72]. However the theoretical risk of promoting breast malignancy or recurrence remains, mediated by mechanisms such as the expression of protumorigenic factors (such as aromatase) by cells within the graft, angiogenesis and the transformation of stem cells within the graft [73]. The concerns regarding aromatase may be reduced by injection into subcutaneous tissue or under the gland rather than into the parenchyma, and angiogenesis is only transient following fat grafting [68]. There is currently no laboratory evidence that cells present within the adipose tissue graft represent any meaningful risk of malignancy [68]. Although it is difficult to extrapolate the results of laboratory studies to the clinical setting, it is unlikely that fat transfer will be adopted universally until longer term clinical studies have provided a more definitive answer. However, the fact that published clinical studies describing outcomes of fat grafting to the breast in more than 2000 patients have not reported any increase in new or recurrent cancers is encouraging [68].

In a level IV study Rigotti and colleagues evaluated 137 patients treated with autologous fat grafting for cosmetic defects or following modified radical mastectomy [74]. All patients had at least three years of follow-up after fat grafting with a median follow-up of 7.6 years. The study evaluated local recurrence of breast cancer during two periods: the period between initial surgery and fat grafting, and the period between fat grafting and follow-up. The breast cancer local recurrence rate during the pregraft period was 9.1 cases per 1000 patient-years compared with 7.2 cases per 1000 patient-years in the period after fat grafting, with no statistical significance between the groups. The outcomes of definitive larger, prospective, multicentre randomised controlled clinical studies and or a robust international registry with long-term follow up with adequate serial pre- and posttreatment radiological examination are eagerly awaited by both patients and the plastic surgical community. Until then, it should be advised that lipofilling should be performed only in experienced hands in the context of cautious oncologic follow-up [75].

CONCLUSION

In this chapter we have demonstrated using the best available evidence that breast augmentation is a process, and that if it is approached with the principles that we have delineated, patients are likely to be highly satisfied, with improved outcomes including the lowest possible complication rate and reoperative requirement.

Chapter 36

BREAST REDUCTION

Gurjinderpal Singh Pahal* and Venkat Ramakrishnan

St. Andrews Centre for Plastic Surgery, Broomfield Hospital, Chelmsford UK

KEY POINTS

- Reduction mammoplasty remains a frequently performed plastic surgical procedure with consistently high patient satisfaction scores.
- Functional disability and impaired quality of life resulting from macromastia can be improved by reduction mammoplasty.
- Postoperative ability to lactate is similar whether a superior, medial, or inferior full-thickness nipple pedicle is used for reduction mammoplasty.
- The risk of post-operative complications is doubled in active smokers.
- Mammographic screening saves 2-2.5 lives for every over diagnosed case overall. In those who are under forty, it is recommended for patients at high risk of breast cancer.
- The evidence currently suggests only a single pre-operative dose of intravenous antibiotic is needed to reduce infection rates.
- The use of adrenaline-containing local anaesthetic solutions decreases significant blood loss and provides analgesia for the patient.
- Vertical scar reduction is associated with a higher surgical revision rate compared with a Wise pattern reduction.
- The majority of members of the American Society for Aesthetic Plastic Surgery use only an inferior pedicle and Wise pattern technique for breast reduction.
- Use of drains does not alter haematoma rate, but in practice most breast reductions have drains placed and nearly half of surveyed surgeons always use them.

“There is no better beginning to the saga of mammoplasties than ‘Once Upon a Time...’ and at its source lies women's eternal dream – beautiful, firm and harmoniously

proportioned breasts – a dream that has inspired painting, sculpture and literature since the dawn of mankind...”

Lalardrie & Mouly, 1978¹

INTRODUCTION

In what could be the first recorded ‘breast reduction’ aimed at improving function, Hippocrates (460–370 B.C.) narrates the legend of Shi’ite women having their right breast amputated by cauterization so that

“...all their strength and power was concentrated in the right shoulder and arm, thus permitting them to handle their swords better”².

Byzantine physician Paulus of Aegina (Alexandria, 625-690 AD) used a crescentic inframammary incision with resection of skin in pendulous cases for "effeminacy of men", or male breast reduction [3]. In 1848 Dieffenbach was probably the first to perform a reduction mammoplasty in a female by reducing the lower two-thirds of the breasts and posterior segment, leaving the scar in the inframammary fold [4].

Reduction mammoplasty remains a frequently performed plastic surgical procedure today. Common indications include bilateral macromastia and for symmetrisation following developmental asymmetry or contralateral post-mastectomy reconstruction. It consistently rates highly for patient satisfaction with 93% of women reporting they would undergo the surgery again [5], and it has been shown to improve body self-image [6].

This chapter aims to present the most up-to-date scientific evidence available for breast reduction surgery rather than to provide the reader with detailed technical guidance. The evidence behind the most popular approaches to these procedures and the opinions of respected experts in the field shall also be presented.

To research this topic, a Medline literature search was performed using the terms ‘reduction mammoplasty’, ‘reduction mammoplasty’ or ‘breast reduction’. Limiting the search to level I evidence (Appendix 1), whilst academically ideal, would identify few publications and exclude many of the most influential practitioners. Therefore papers of all evidence levels have been assessed based as much on their importance as their scientific methodology.

PATHOPHYSIOLOGY

Women with breast hypertrophy have oestrogen levels within normal laboratory limits and a normal number of oestrogen receptors [7], suggesting that some women may be hypersensitive to circulating oestrogens and/or demonstrate an abnormal end-organ response to it. Thelarche, pregnancy and menopause may also be responsible for hypermastia, further supporting the oestrogen-sensitivity theory. In addition, the global obesity epidemic has resulted in breast hypertrophy secondary to increased adipose tissue rather than glandular hyperplasia, and fat now accounts for 48-61% of breast reduction specimens [8, 9]. Finally, a rare but important condition to consider is juvenile virginal hypertrophy of the breast

(gigantomastia), for which definitions vary but include resections specimens of more than 1800g per breast or of 3% total body weight [10, 11].

SURGICAL ANATOMY

Comprehensive knowledge of the neurovascular anatomy of the breast is prerequisite to understanding the design choices available for reduction mammoplasty and to minimise nipple areolar complex (NAC) necrosis and sensory loss.

The breast is a superficial ectodermal structure with a rich blood supply, receiving contributions from the internal mammary artery medially, the thoracoacromial and thoracodorsal arteries superiorly, branches of the lateral thoracic artery and multiple deep intercostal perforators through and below the pectoralis musculature [12] (Chapter 34, Figure 1).

Taylor et al. described the breast as having a predominantly superficial arterial supply and venous drainage through the subdermal plexus [13], reinforcing the importance of a maintained dermal connection to the nipple-areolar complex (NAC) pedicle. Hall-Findlay [14] also describes a superficial arterial input to the breast with the exception of one large deep perforator arising from the internal mammary artery at the level of the fifth or sixth intercostal space. It usually perforates the pectoralis musculature medial to the breast meridian slightly above the infra-mammary fold (IMF) and carries venae comitantes with it.

There is at present a lack of literature comparing the vasculature of different NAC-bearing pedicles in detail. O'Dey et al. [15] examined the architecture of the arteries supplying the breast and their contribution to the blood supply of the NAC on seven female cadavers (fourteen breasts) following vessel filling. Four arterial sources were found to be primarily responsible for the blood supply to the NAC. In descending order of reproducibility these were branches originating from the lateral thoracic artery, the internal mammary artery, the anterior branches of the intercostal arteries and those deriving from the highest thoracic arteries.

The NAC is usually innervated by the 3rd, 4th and 5th anterior cutaneous nerves and the 4th and 5th lateral cutaneous nerves [16] (Chapter 34, Figure 2). The lateral cutaneous branch of the 4th intercostal nerve is considered uniquely responsible for NAC sensation [17] (Figure 1). The deep branch of the lateral 4th intercostal nerve has been shown in cadaveric studies to run medially above the pectoralis fascia until the mid-portion of the breast, where it then runs superiorly towards the NAC [18]. Maintaining a full thickness medial pedicle and not exposing the pectoralis fascia may therefore explain why the medial pedicle technique maintains nipple sensation equivalent to that of the lateral pedicle technique [13].

The subcutaneous layer of adipose tissue in the breast is traversed by Cooper's suspensory ligaments. These are the connective tissue support structures within the breast and extend obliquely to the skin surface from the deep pectoral fascia. The attachments stretch with pregnancy, obesity and aging, resulting in excess breast mobility and ptosis. Finally, as a mammary gland, the breast comprises lactiferous ducts each supplied by glandular breast parenchyma and draining into the nipple.

AIMS OF SURGERY

In 1928 Biesenberger [19] outlined eight aims of reduction mammoplasty that remain relevant today. They are:

1. The breast should be lifted to a youthful and natural form in proportion to other parts of the body.
2. The two breasts should be symmetrical.
3. The nipple and areola should be translocated to an appropriate location.
4. The blood supply to nipple and areola should not be jeopardized.
5. The function of the breast should be preserved.
6. The scars should not be visible through normal clothing or be above the areola.
7. The operation must be applicable to all forms of deformity.
8. The procedure should be a one-stage operation.

Reduction mammoplasty aims to improve symptoms by decreasing the volume of breast tissue. The technique should yield a predictable and improved breast shape whilst providing parenchymal support to enable longevity of the result. Vascular and neural integrity of the NAC should be maintained and the NAC should be repositioned to its anatomically correct position.

SURGICAL INDICATIONS AND PATIENT SELECTION

Disproportionate upper body weight resulting from breast hypertrophy can cause functional disability and adversely affect quality of life. Multiple studies have shown that reduction mammoplasty provides symptomatic relief and improves the quality of life for patients with macromastia [20]. Such women often have a poor posture and complain of musculoskeletal symptoms such as neck, back and shoulder pain, as well as heaviness of the anterior chest wall. They may have shoulder indentations and ulceration from the strap of the brassiere due to the weight of their breasts and sometimes suffer from intertrigo, acne and inframammary hidradenitis.

Hypertrophic breasts themselves may be ptotic and exhibit prominent veins, stretch marks and an enlarged NAC. Occasionally the patient may complain of upper limb paraesthesiae, particularly in the ulnar nerve distribution, secondary to pressure on the brachial plexus.

The social stigma of breast hypertrophy should not be underestimated. Inability to participate in sport and exercise, sexual harassment and ill-fitting clothing are common complaints. The psychological benefits of restoring proportion between the breasts and overall physique are difficult to quantify, but many surgeons believe they are considerable and numerous patient satisfaction studies of reduction mammoplasty have documented favorable results [21-28].

In North America most insurance carriers will not reimburse for reduction mammoplasties in which less than 1000g tissue is resected. Spector et al. [29] examined the effect of smaller reduction mammoplasties on symptoms and quality-of-life. A total of 59

patients underwent reduction mammoplasty of less than 1000g, and all patients were given a questionnaire designed to evaluate macromastia-related symptoms and quality-of-life issues, preoperatively and three to twelve months postoperatively.

The investigators found that smaller reduction mammoplasties significantly reduced all macromastia-related symptoms assessed, including pain in the upper and lower back, neck, arms, shoulders, hands and breasts, as well as reducing headaches, rashes, itching and painful bra strap grooving. Furthermore, reduction mammoplasty resulted in significant improvement in all quality-of-life factors analyzed, including difficulty buying clothes and bras, difficulty participating in sports and difficulty running. The authors concluded that reimbursement for reduction mammoplasty of less than 1000g was justified.

Thoma et al. [30] assessed the health-related quality of life experienced by 52 breast reduction patients using four reliable and validated health-related quality-of-life measures completed at one week and one day before surgery and at one, six, and twelve months afterwards. For all patients, mean scores for all quality-of-life instruments increased from the preoperative assessments to the postoperative assessments. The effect of surgery was equivalent to an expected lifetime gain of 5.3 quality-adjusted life years (equivalent to each patient living an additional 5.3 years in perfect health). The authors concluded that there was no justification for the ongoing restriction or denials of third-party payments based on body mass index.

PREOPERATIVE ASSESSMENT

General

As well as a standard medical and surgical history, a history of bleeding tendency and of factors that may compromise wound healing, such as smoking and diabetes, should be noted and measures taken to optimise preoperative physiology. Use of hormone-based medications, blood-thinning agents and the presence of any allergies should be documented. Importantly, the patient's expectations of surgery and desired post-operative bra size should be explored so that unrealistic expectations can be addressed at this stage.

General examination of pertinent systems is followed by a tailored breast examination with the patient standing and arms hanging by the sides at ease. Particular attention should be paid to breast asymmetry, chest wall abnormalities, kyphosis or scoliosis, breast lumps, masses, scars, skin dimpling, nipple discharge, and the grade of breast ptosis. The axillae and supraclavicular areas should be palpated for lymphadenopathy and accessory breast tissue and the rest of the abdomen and pelvis examined for accessory breasts.

Important measurements to note include bra size, sternal notch to nipple distance, nipple to inframammary fold (IMF) distance, width of the nipple areolar complex (NAC) and BMI. Any subjective alterations in nipple sensation should be documented. Finally, sequelae of macromastia such as poor posture, notching or ulceration of the shoulders from the straps of the brassiere and submammary intertrigo should be noted. Pre-operative photographs from the neck to the waist in three views (head on, oblique and lateral) complete the pre-operative consultation.

Age

Shermak et al. [31] investigated the impact of age on the outcome of breast reduction using multiple logistic regression analysis in 1192 consecutive patients (2156 breast reductions) with an average age of 36, performed over ten years by seventeen plastic surgeons at one institution. Women older than fifty years were significantly more likely to experience infection (odds ratio 2.7) with non-significant trends toward wound healing problems (odds ratio 1.6) and re-operative wound debridement (odds ratio 5.1). There was no association between age and the development of fat necrosis or seroma. They concluded that patients older than fifty have impaired breast reduction outcomes, particularly infection, that may negatively impact wound healing, and postulate that hormonal deficiency may partially account for this finding.

However, as highlighted by Alderman et al. [32], several other surgeon and patient factors that could be correlated with post-operative infections were not included, such as use of peri-operative antibiotics, length of surgery, patient temperature, operating room traffic, the individual surgeon, type of reduction technique and reduction volume, and it is unclear why this information was omitted from the analysis.

Obesity

The effect of obesity on complication rates following reduction mammoplasty is unclear from the literature. Four retrospective studies (a total of 1033 women) concluded that obesity had no impact on the risk of complications [33-36] whereas four other retrospective studies (a total of 1514 women) concluded that increasing obesity lead to increased complication rates [37-40].

The Maintenance of Certification (MOC) program encourages surgeons to engage in, and measure up to, a comprehensive set of standards designed to help them maintain high professional standing, participate regularly in continuing medical education, remain current in critical knowledge areas, and perform well in their surgical practices. Since 2007, the American Board of Plastic Surgery has accumulated data on 606 surgeons, reporting on 6461 breast reductions. Most recently, Kerrigan et al. [41] have analysed the MOC data set using logistical regression. They conclude that a BMI of over thirty is a significant predictor of adverse events and parenchymal resection of 1301-1900g was also a significant predictor of increased complications. Obesity with a BMI exceeding forty carried a significant risk of re-operation.

Smoking

According to Bartsch et al. [42], an active smoking history doubles the risk of developing post-operative wound healing problems, defined in their study as the absence of a stable dry non-inflamed wound requiring no dressings within ten days of surgery. Padubidri et al. [43] reports an overall breast reconstruction complication rate in smokers of 39%, compared with 25% in ex-smokers and 26% in non-smokers. Complications were significantly more frequent

in smokers, and smokers undergoing mammoplasty should be urged to stop smoking for at least three weeks prior to surgery.

Ability to Breast-Feed

The reproductive history of the patient is important, noting whether the patient succeeded in breast-feeding previously and any possible wish to do so in future. It should be explained that any significant resection of sub-areolar breast tissue will decrease the amount of breast tissue that can contribute to lactation. Studies have demonstrated that approximately seventy percent of patients can breast-feed after breast reduction but that only thirty percent do, similar to the rates in a population that has never had surgery.

Using a patient-completed questionnaire, Cruz Korchin et al. [44] compared ability to breast-feed in 164 patients who had undergone mammoplasty with different pedicle types (48 superior, 59 medial, and 57 inferior full-thickness dermoglandular pedicles) with a control group of 151 women of child-bearing age with macromastia but no prior breast surgery. They found no significant difference between any of the groups - successful breast-feeding, defined as breast-feeding for two weeks or more, was observed in 62% of the control group versus 62% for superior pedicle, 65% for medial pedicle and 64% for inferior pedicle breast reductions.

The ability to lactate (i.e., produce milk) and the ability to breast-feed successfully (i.e., satiate the feeding demands of an infant) should be distinguished. Reassuringly, no significant difference was found between any of the mammoplasty groups and the control group in the need to supplement breast-feeding (34% in the control group versus 38%, 38% and 35% in the superior, medial and inferior pedicle techniques respectively). Finally, it is worth emphasising that Cruz Korchin specifically refers to *dermoglandular pedicles* in this study, and it is unlikely that *dermal* pedicle breast reductions will retain much breast-feeding potential.

Screening Mammography

It is accepted that screening mammography guidelines should be followed in the pre-operative course of patients undergoing reduction mammoplasty. Such guidelines, however, remain controversial in the general female population and false-positive findings can result in overdiagnosis, necessitating additional imaging, biopsies and needless harm [42]. The American Cancer Society [45] and the American Congress of Obstetrics and Gynaecologists [46] recommend annual mammography in women over forty years old. The US Preventive Services Taskforce[47] advises against routine annual screening in women aged 40-49 and advocates biennial screening mammography for women aged 50-74 years. The NHS Breast Screening Programme provides free breast screening every three years for all women aged fifty and over. The programme is now phasing in an extension of the age range of women eligible for breast screening to those aged 47 to 73. In September 2000, research was published which demonstrated that the NHS Breast Screening Programme had lowered mortality rates from breast cancer in the 55-69 age [48]. In 2010, Duffy et al. [49]

demonstrated that the benefit of mammographic screening (lives saved) exceeded harm caused (overdiagnosis), with 2-2.5 lives saved for every overdiagnosis.

The lifetime risk of breast cancer is one in eight, and occult carcinoma has been detected in 0.06% to 0.4% of breast reduction specimens despite normal preoperative mammography. For instance, Colwell et al. [50] examined the incidence of breast cancer in breast reductions specimens in one institution over a fourteen-year period. Six cancers were detected from 800 reduction mammoplasties performed between 1988 and 2001 (0.8%). Three were invasive (0.4%) and three were ductal carcinoma in situ (0.4%). Thus, a thorough breast history must be obtained including family history of breast cancer, previous open or percutaneous biopsies or surgery to the breast, previous abnormal mammograms, history of nipple discharge and any recent change in breast shape.

Some practitioners take the view that, since a large proportion of their patients will go on to develop cancer, it is worthwhile using the resection specimens opportunistically to establish that cancer was not present at the time of surgery, thereby avoiding a future possible claim of negligence for failing to diagnose cancer at the earliest opportunity.

SURGICAL TECHNIQUE

The nomenclature used for reduction mammoplasty techniques can be confusing. A clear distinction should be made between the skin resection pattern (e.g., vertical, inverted 'T' periareolar, limited horizontal scar, no vertical scar etc.) and the choice of pedicle used to maintain the neurovascular supply to the NAC (which ultimately governs the parenchymal excision). Each may be selected independently. Whilst reducing breast volume to improve symptoms is the desired goal, this should be achieved by utilising a technique that maintains blood and neural supply to the skin and NAC of the breast, preserves the ability to breast feed and ultimately results in a cosmetically pleasing breast shape that is maintained over time. Literature review does not point to any right or wrong answer as to which technique to use under particular circumstances; instead it is evident that patient selection combined with surgeon's expertise are both key to success.

Use of Infiltration

The use of adrenaline-containing local anaesthetic solutions appears to decrease blood loss and the need for blood transfusion, as well as providing analgesia for the patient. Noone [51], Thomas [52] and Metaxotos [53] advocate the use of adrenaline-containing local anaesthetics. Thomas et al. compared outcomes with or without preoperative infiltration of 180-200ml normal saline containing 1:500,000 adrenaline in a series of 100 breast reductions (fifty patients), with groups matched for age and co morbidity. Blood loss, measured by the fall in postoperative haemoglobin, was significantly less when infiltration was used. The clinical significance of this finding, however, is unclear as the authors do not correlate the fall in haemoglobin with their patients' cardiovascular parameters.

Metaxotos et al. conducted a randomised, double-blind, placebo-controlled trial to evaluate the effect of preoperative adrenaline-containing local anaesthesia infiltration on peri-

and postoperative bleeding and postoperative pain in 24 consecutive patients undergoing breast reduction. One breast was infiltrated with bupivacaine and adrenaline solution, and the other with the same volume of normal saline. Peri-operative blood loss was calculated by weighing swabs, and the postoperative drainage from suction drains was measured at 3, 24 and 48 hours. Postoperative pain was assessed using visual analogue scales and verbal response scores at three, six, ten and 24 hours post-infiltration. There was a significant reduction in both peri- and postoperative blood loss ($p < 0.01$ and $p < 0.05$ respectively) and pain on the side receiving infiltration ($p < 0.01$).

Use of Antibiotic Prophylaxis

Several studies have yielded contradictory findings as to the benefit of antibiotics in breast reduction. Ahmadi et al. [54] prospectively compared microbiology cultures from fifty reduction mammoplasty patients divided into three groups: those who received no antibiotics, a single dose of preoperative antibiotics or both pre- and postoperative antibiotics. Patients were generally young (average age 34 years), the average body mass index (BMI) was 32 and patients had no history of diabetes mellitus, peripheral vascular disease, previous breast surgery or use of steroids or tobacco.

On microbiological culture, 55% of patients exhibited growth in one or both breasts, most commonly of *Staphylococcus epidermis* (90%) followed by *Corynebacterium diphtheria* (7%), and *Enterobacter* (3%). Patients with positive cultures were more likely to have active infection than those with a negative culture, but there was no significant difference in infection rate between any of the groups. There was, however, a significant reduction in the occurrence of delayed wound healing in the group that received preoperative antibiotics only, and there was a significant association between delayed wound healing and infection. The authors concluded that prophylactic antibiotic use in breast reduction does not significantly alter infection rate, but a single preoperative dose significantly improves wound healing (presumably through an effect on subclinical infection).

Veiga-Filho et al. [55] prospectively randomized 100 women to receive either no antibiotics or preoperative antibiotics and a six-day post-operative course, with the same operative parameters as Ahmadi et al. (surgery performed by the same surgical team under general anaesthesia, using a Wise pattern scar incision and no drains). All patients were discharged on the first postoperative day and followed up weekly for thirty days by a surgeon blinded to the study group.

They found that the infection rate was significantly lower in the study group receiving antibiotics (2% vs. 14%), but the study had several limitations: for instance, the non-antibiotic group consisted of older patients with a higher total resection weight, either of which could have contributed to the infection rate. Despite this, and combined with the previous study, it seems appropriate to give patients a single pre-operative dose of intravenous antibiotic. It is clear that future randomized controlled trials are needed to confirm the efficacy and cost-effectiveness of antibiotic use in reduction mammoplasty, since injudicious use can suppress natural host flora, result in microbial resistance and have implications on cost and potential allergic reactions.

The Wise Pattern Reduction Mammoplasty

The inverted-T, or Wise pattern, skin excision pattern can be used with any pedicle. It is most commonly combined with the inferior pedicle technique, as described by Robbins in 1977 [56], although the senior author's preference is for a superomedial pedicle (Figure 1). Advantages of the inferior pedicle technique include a predictably reliable pedicle, ease of teaching and versatility, ranging from very small reductions/mastopexies to larger reductions [57-60]. This has made it the preferred method of breast reduction worldwide for the past forty years [61-64].

Figure 1. Surgical sequence for Wise pattern reduction mammoplasty with a superomedial pedicle. The markings are determined preoperatively with the patient standing. The pedicle is deepithelialised, inferior medial and lateral wedges excised and medial and lateral breast pillars reapproximated to create a pleasing breast cone, prior to final closure.

Figure 2. Pre- and post-operative appearance of Wise pattern inferior pedicle breast reduction.

The technique does have drawbacks, however, including a large inframammary scar (which may become stretched or hypertrophic) and the phenomenon of 'bottoming-out' or pseudoptosis [65] referred to by Claude Lassus as "*Sein en Sabot*" or "*clog aspect*".

According to Hall-Findley [14], the inverted-T techniques usually rely on the skin brassiere to shape the breast, undermining the skin and leaving behind the heavy inferior pole of the breast that invariably bottoms-out as the skin stretches.

Niranjan modifies the technique by use of a 'dermal hammock' that is a triangular-shaped dermal extension of the inferior pedicle. This is secured to the pectoralis fascia to support the pedicle and theoretically prevent bottoming out. There is, however, no long-term published data to support this modification at present.

Cruz-Korchin et al. [66] prospectively compared the outcomes of 208 patients randomised to undergo either inferior pedicle Wise pattern reductions (group I) or medial pedicle vertical pattern reductions (group II) in moderate resections averaging 500g per breast. Outcome measures were self-assessed patient satisfaction six months postoperatively, revision rates and complication rates.

There was no significant difference between the groups in age, body mass index or the amount of tissue excised. Group I required no surgical revisions, whereas there was an eleven percent revision rate for dog-ears in Group II. Other complications occurred with similar frequency in both groups. Patients' evaluations of breast size, shape, symmetry, nipple sensation, symptom relief, ease of brassiere/clothing fitting, and overall satisfaction were similar. The vertical mammoplasty was rated significantly higher by patients with regard to scars and overall aesthetic results. The authors concluded that patients are less disappointed with the scars following a vertical scar breast reduction but are more likely to require surgical revision than those who have a Wise pattern reduction.

Okoro et al. [67] surveyed 5112 members of the American Society of Plastic Surgeons on their preferences, practices and opinions of various breast reduction techniques. Around half of those surveyed responded. Most used preoperative antibiotics (93%), intra-operative deep venous thrombosis prophylaxis (92%), general anaesthesia (97%), an inferior pedicle (69%), and usually (more than 75% of the time) performed surgery on an outpatient basis (61%). The authors concluded that the inferior pedicle Wise pattern remained the most popular but use of other techniques was increasing. They also concluded that plastic surgeons were increasingly aware of the risks of deep venous thrombosis.

Rohrich et al. [68] surveyed 1500 members of the American Society for Aesthetic Plastic Surgery, of whom 554 responded. A little over half (56%) of their respondents used only the inferior pedicle and Wise pattern techniques, whereas 6.9% of the respondents used only limited incision techniques. Most surgeons reported that they did not anticipate changing their practices to accommodate advances in limited incision techniques, although 89% believed that newer limited incision and liposuction techniques were trends that would be here to stay.

The Vertical Scar Reduction Mammoplasty

In 1964 Claude Lassus designed the vertical scar incision pattern, subsequently reported in 1970 as '*A technique for breast reduction*' [69]. He modified the technique in 1986 and again the next year to achieve a skin excision pattern that left a single vertical scar above the IMF [70, 71]. A similar skin incision is used in the Lejour vertical mammoplasty, and some authors credit Lejour for bringing the vertical mammoplasty concept into the mainstream of plastic surgery [65]; in 1994 she published her results on 153 reduction mammoplasties using

this technique combined with liposuction, and in 1999 she updated her experience on 324 reductions performed in 167 patients [72].

Advocates of the vertical scar technique combined with a superomedial pedicle list the benefits as a shorter scar with decreased scar hypertrophy, retained upper pole fullness, more extensive lateral parenchymal resection (avoiding axillary fullness) and a more desirable surgical result with greater projection and longevity [73]. The breast is coned rather than being pushed up and flattened and the vertical elliptical excision means that the medial and lateral pillars are brought together. Approximation of the parenchymal pillars rather than reliance on the skin envelope results in, it is claimed, longevity and a more aesthetic shape to the reduced breast. However, no long-term studies compare the longevity and shape of one technique with the other.

The superomedial vertical scar technique has been criticised for being restricted to cases of mild to moderate mammary hypertrophy and is considered less intuitive and difficult to learn when compared with inverted-T scar reduction mammoplasties. Surgeons report increased complication rates with higher volume parenchymal resection and some remain hesitant to apply the superomedial pedicle vertical scar technique to large volume mammoplasties [74-76]. Furthermore, concern over NAC vascular compromise during pedicle rotation has prompted some surgeons to limit this technique to reductions less than 1000g[75,77].

Lista et al. [78] reported the largest series (250 consecutive patients) of vertical scar reduction mammoplasties performed by a single surgeon over a three-year period. A 'mosque dome' skin-marking pattern was used with transposition of the NAC on a superior or medial dermoglandular pedicle. The average reduction per breast (including liposuction) was 636g (range 60 to 2020 g) and complications were minimal (5.6% of breasts), with no nipple loss, attesting to the safety of this technique. They conclude that this technique has been applied to breast reductions of all sizes and has consistently produced good breast shape, with an operation that is quicker to perform and leaves less scarring than standard breast reductions.

Hall-Findlay [73] concludes that medial or superomedial pedicle vertical breast reduction is simple, efficient and reliable and the desirable superior portion of the breast is preserved whilst the undesirable inferior and lateral portion of the breast is removed. The result is a shorter scar and a post-operative breast that maintains an aesthetic shape over time by relying on the healing medial and lateral breast pillars for shape rather than the skin brassiere.

Choice of Pedicle

A variety of pedicles have been described over the years that use the inverted-T shape scar pattern, including the lateral pedicle of Skoog [79], Strombeck's horizontal bipedicle and lateral pedicle [80], the vertical bipedicle of McKissock [81], the inferior pedicle as already discussed and Weiner's superior pedicle [82]. It is clear, however, that the inferior and central mound techniques have stood the test of time and remain safe and reliable, albeit with their own aesthetic limitations.

Nipple sensation is derived laterally from the fourth intercostal nerve. As previously discussed, the deep branch of the lateral fourth intercostal nerve runs across the breast above the pectoralis fascia until the mid-portion of the breast, where it travels superiorly towards the NAC. This may explain why full thickness pedicles other than the lateral pedicle can also

successfully preserve nipple sensation, so long as exposure of the pectoralis fascia is avoided [18]. Davidson et al. [83] compared safety, reliability and operative time of the superomedial and inferior pedicle techniques amongst 215 patients with an average BMI of 29. There were no cases of nipple loss and no significant difference in operating time.

Septum-Based Mammoplasty

The septum-based mammoplasty is an evolution of the lateral and medial pedicle techniques to improve sensitivity of the NAC after reduction mammoplasty and to enhance blood supply to the pedicle by preserving intercostal perforators within the septum [84]. The pedicle is based on a horizontal septum described by Würinger [85,86], which attaches the NAC to the thoracic wall at the level of the fifth rib (Figure 3). Branches and perforators from the intercostal, thoracoacromial, and lateral thoracic vessels as well as the deep branch of the fourth intercostal nerve are included within this septum.

Figure 3. The septum-based mammoplasty aims to preserve the deep branch of the 4th intercostal nerve along with its horizontal vascular pedicle.

As Hamdi states,

“It is very difficult to invent a new technique in plastic surgery, and it is said that something new is something old that has been forgotten, so we still adopt and improve old ideas in order to incorporate them into our contemporary techniques” [87]

Thus, the contribution of Skoog merits particular recognition as the first to describe the lateral dermoglandular pedicle.

In Hamdi's series [88], 110 consecutive patients underwent septum-based breast reduction over a seven-year period. The mean nipple-to-sternal notch distance was 33cm (range 22 to 45 cm), mean resection was 658g (range 160 to 1980g) and nipple elevation averaged nine centimetres (range three to seventeen centimetres). Complications included a retroareolar hematoma in three breasts and total areola necrosis in one (0.5%) as a result of an infection in a diabetic patient. Limited wound dehiscence occurred in fifteen breasts (7.7%), secondary scar revision was needed in ten (9%) and one patient required a revision. Most of the complications occurred in the first fifteen patients and was attributed to the learning curve of the procedure.

Use of Surgical Drains

Two important studies show that the incidence of adverse events is not significantly altered by the use of drains. Collins et al.[89] randomly drained one breast in 150 patients undergoing bilateral breast reduction. The majority (141) of patients had inferior pedicle reductions. There was no mention of antibiotic use or whether the infiltrate contained epinephrine. Haematomas occurred in seven patients (4.6%) and there was no difference between the drained and undrained sides.

Similarly, Corion et al. [90] randomised 107 patients undergoing bilateral breast reduction to have bilateral drains (55 patients) or no drains (52 patients). Neither antibiotics nor wetting solution were used. Again, their rates of adverse events were similar in each group. Despite this evidence, a recent review of practice reported in the MOC shows that over half of all breast reductions performed had drains placed and 44% of surgeons always use drains, whereas 31% never use them [41].

EXAMINATION OF HISTOPATHOLOGICAL SPECIMENS

Breast reduction specimens are routinely sent for histopathological analysis but there is little evidence to guide best practice [91]. The lifetime risk of breast cancer is one in eight, and it is not uncommon for invasive or in-situ carcinoma to be detected in reduction mammoplasty specimens despite normal mammograms [41]. The most recent analysis of the largest series of breast reduction specimens by Kerrigan et al. [92-97] concludes that 0.5-4% of surgical specimens result in a diagnosis that may initiate further treatment; breast reduction specimens from women older than forty years, as well as higher risk women of any age (*BRCA* genes, positive family history of breast cancer) should be studied microscopically.

The rate of abnormal findings depends on the extent of pathological examination. Nielsen et al. [98] performed extensive pathological examinations (three millimetre cuts, with 200 or more blocks per specimen) on autopsy breast specimens, finding a 14-16% incidence of unsuspected invasive breast cancer or ductal carcinoma in situ. Pathologic findings appeared related both to age and the extent of histologic investigation. Examination of three areas of tissue rather than one demonstrated a higher rate of pathologic findings in women older than

forty years but not in younger women. Bondeson et al. [99] reviewed pathologic findings in breast specimens from women younger than thirty years and found no significant abnormality. They suggested that microscopic examination was unnecessary in this group.

In five separate cohorts containing breast reduction specimens from 560, 562, 800, 813, 866 and 2488 patients respectively, between 0.5 and 4% of surgical specimens contained a diagnosis that could initiate further treatment [92-97]. Colwell et al.[93] examined the incidence of breast cancer in 800 reduction mammoplasties performed at their institution over a fourteen-year period. Six cancers were detected (0.8%) of which three were invasive (0.4%) and three were ductal carcinoma in situ (0.4%). Stratified by indication for surgery, there was a trend toward higher detection rates in the reconstruction group – that is, patients having symmetrising breast reduction following a previous breast reconstruction for cancer - compared with the macromastia or congenital asymmetry groups (1.2% vs. 0.7% vs. 0% respectively). Preoperative mammography was negative for masses and suspicious microcalcification in all patients. They conclude that reduction mammoplasty involved a small but definite risk of detecting previously undetected cancer in the resection specimen.

Clark et al. [97] conducted a single-centre retrospective chart review examining the incidence of benign and precancerous lesions in breast reduction specimens over a five-year period. Of the 562 patients who underwent reduction mammoplasty, 53% had non-proliferative or proliferative breast lesions (non-proliferative disease is not associated with an increased risk of breast cancer, whereas proliferative disease without atypia results in a small increase in risk – RR 1.5-2). A further 25 patients (4.4%) had a specimen containing atypical ductal or lobular hyperplasia (proliferative disease with atypical hyperplasia is associated with a greater risk of cancer development - RR 4-5), six patients (1.1%) had ductal carcinoma in situ and four patients (0.7%) had lobular carcinoma in situ. No occult invasive breast cancer was identified in the breast reduction specimens, but one patient with ductal carcinoma in situ was found to have invasive breast cancer on completion mastectomy (0.2%). Their study demonstrates the importance of systematic analysis of breast reduction specimens to help identify and guide the management of patients with increased risk of breast cancer following reduction mammoplasty.

CONCLUSION

This chapter offers the reader a comprehensive appraisal of the current evidence-based literature available for reduction mammoplasty. As well as including the highest quality evidence, as defined by accepted ‘level one’ research standards, the opinions of experts in the reduction mammoplasty arena have been included. Having appraised the evidence in detail, it is apparent that advocates of one preferred technique over another have years of experience, as well as evidence, to support their decision. The common goals of breast reduction remain the same however – to yield aesthetically pleasing breasts with minimal scarring, using a technique that will preserve nipple sensitivity, respect breast anatomy and offer longevity as far as shape is concerned.

As with all plastic surgical procedures, surgery should be bespoke to suit the needs of the patient, as well as satisfying realistic expectations. Aside from the pedicle and skin pattern choice, evidence for and against the use of drains, antibiotics and adrenaline-containing

infiltration has been discussed at length, and patient factors that point towards unfavorable outcomes, such as smoking, obesity and age, have also been deliberated. The plethora of available evidence is reassuring to a degree, however it also indicates the learning curves, both initial and ongoing, that plastic surgeons face throughout training and beyond.

Chapter 37

LIPOSUCTION

Reza Nassab*

Lancashire Teaching Hospitals NHS Foundation Trust, UK

KEY POINTS

- Wetting solutions have allowed more extensive liposuction without the associated blood loss. The tumescent and superwet techniques both have an estimated blood loss volume of one percent of the aspirated volume, compared to reported rates of 20-45% for the dry technique.
- The main techniques are suction (SAL), power (PAL), ultrasound (UAL) and laser assisted (LAL) liposuction.
- PAL has been shown to be quicker to perform with less pain, bruising and oedema when compared with SAL.
- UAL has been shown to result in less blood loss than SAL.
- A small number of case series have shown the potential benefit of skin retraction following LAL.
- Despite the variety of liposuction techniques, almost all comparative studies of the liposuction assisted devices revealed no significant difference in terms of aesthetic outcome.

HISTORY OF BODY CONTOURING AND LIPOSUCTION

On February 28, 1926, the French surgeon Charles Dujarier attempted to remove fat from the legs of one Suzanne Geoffre, a fashion designer who was unhappy with the heaviness of her calves. For the first time, ladies fashion exposed legs below the knees, and slender calves and ankles became highly sought after. The attempt, however, tragically resulted in amputation of a limb, and it was fifty years before the procedure resurfaced again.

* Corresponding Author's Email: rsnassab@gmail.com.

In the early 1970s, Schrudde described ‘lipexeresis,’ which was a technique of creating subcutaneous tunnels with scissors and then removing fat with curettes and suctioning the remaining particles after irrigation. In 1976, Fischer and Fischer developed the addition of suction to extract subcutaneous fat with the use of sharp cannulas[1]. Dr Illouz introduced the blunt cannula for fat removal in France in 1977[1,2]. The next important milestone in liposuction was the use of wetting solutions by Dr Illouz, which heralded lower blood loss and removal of larger amounts of fat[1,2]. The technique of liposuction was introduced to the United States in the early 1980s[3]. In 1987, Klein introduced the tumescent technique of liposuction that allowed liposuction to be performed under local anaesthesia with reduced blood loss[2]. Since the advent of traditional suction assisted liposuction (SAL) there have been a number of advances in techniques and technologies to assist the procedure, including power-, laser-, ultrasound and radiofrequency-assisted devices.

In 2011, the International Society for Aesthetic Plastic Surgery reported that over 1.2 million lipoplasty procedures had been performed globally, making it the most common cosmetic procedure worldwide[4]. Liposuction is also the most commonly performed cosmetic surgical procedure in the United States according to the American Society for Aesthetic Plastic Surgery (ASAPS)[5].

This chapter explores the various facets of liposuction and reviews the evidence supporting the different techniques that are commonly used.

LITERATURE SEARCH

A search for relevant studies was undertaken using Pubmed up to January 2013. The medical subject headings or MeSH terms used for the search included: liposuction; lipoplasty; lipolysis; infiltration; suction assisted; power assisted; laser assisted; ultrasound assisted; water assisted; radiofrequency assisted and VASER. Combinations of these terms were also used to maximise the return of results. The studies identified were then classified according to the level of evidence for key clinical recommendations using the American Society of Plastic Surgeons Levels of Evidence Rating Scale for Therapeutic Studies (Appendix) [6]. The studies with the highest level of evidence have been included in this review.

KEY STEPS

The process of liposuction may be considered as a number of key steps, which include:

- Preoperative assessment and marking
- Anaesthesia
- Infiltration using wetting solutions
- Incisions
- Liposuction, fat fragmentation and emulsification using various devices
- Closure and dressings
- Postoperative care

Anaesthesia

The introduction of tumescent infiltration allowed liposuction to be performed without general anaesthesia. Liposuction is commonly performed using both general and local anaesthesia with or without sedation. There has also been a move to perform liposuction as an office-based procedure in many parts of the world. Since the original suction lipoplasty was described there have been a number of devices developed to assist with liposuction. The lipoaspirate comprises of a supernatant fat layer and infranatant aspirate. We shall review these in detail and highlight the evidence behind their use. We also review the evidence behind new approaches to body contouring such as water assisted liposuction and radiofrequency liposuction. We conclude by reviewing some special considerations in liposuction such as large volume liposuction and combination procedures.

Infiltration and Wetting Solutions

The introduction of wetting solutions in lipoplasty is credited to Dr Illouz [1,2] and has become standard practice for liposuction. Numerous studies in the literature explore the various solutions used in practice.

Dry

The dry technique, popularised by Fournier and Otteni [2], was the first method of liposuction, in which patients underwent insertion of the liposuction cannula under general anaesthesia without any infiltration. The aspirate would typically contain approximately 20-45% blood, thus limiting the amount of fat that could be removed without the need for transfusion [7]. Triana et al. conducted a large retrospective series comprising more than 26,000 patients undergoing various types of liposuction. In their series, anaemia (which was not defined) was found in two thirds of patients (4760 of 7140 patients) undergoing dry liposuction compared to 0.08% of those having tumescent liposuction [*Level IV Evidence*][8]. Consequently dry liposuction is not frequently used today due to the significant associated blood loss.

Wet

In 1983 Illouz reported his series of over 3000 cases of ‘wet’ liposuction, infiltrating with hypotonic hyaluronidase solution to emulsify fat and facilitate aspiration[9]. The technique consisted of infusion of 100-300ml of fluid into each treatment site regardless of the intended volume of fat removal, and had the effect of reducing the aspirated blood volume to 10-25%[7]. In 1984, Hetter added low-dose epinephrine to the wetting solution in order to reduce blood loss to less than five percent [10].

Superwet

Fodor introduced the concept of the ‘superwet’ technique, which uses an infiltration to aspiration ratio of 1:1[11] – that is, one millilitre of infiltrate is infused for every millilitre of fat to be aspirated. The reported blood loss with this technique ranges from one to four percent of the aspirate[7].

Tumescent

In 1987, Klein described the tumescent technique, which uses larger volumes of infiltrate prior to liposuction [12]. Typically, three to four millilitres of infiltrate would be used for every millilitre of aspirate. In a series of 112 patients, Klein reported that the haematocrit would drop by one percentage point for each litre of fat removed using the tumescent technique [13].

Local Anaesthesia in Wetting Solutions

Numerous studies have explored the safe dose of lidocaine that can be administered during liposuction. In general, the usual recommended maximum dose for lidocaine with epinephrine is 7 mg/kg [7,14], but published reviews have demonstrated safe use of wetting solutions utilizing much higher doses [14]. In liposuction there are a number of factors that contribute to the safe use of higher doses of lidocaine. Firstly, systemic absorption from fat is intrinsically slow. Secondly, absorption is further slowed by vasoconstriction caused by use of epinephrine-containing solutions. Finally, some of the wetting solution is re-aspirated during liposuction. The current recommended safe limit in liposuction is 35 mg/kg of lidocaine when used with epinephrine, although safe use of doses up to 64 mg/kg have been reported [14-16].

A comparative study by Perry et al. assessed the effectiveness of lidocaine on postoperative analgesia. In their ten patients liposuction was performed using a wetting solution that contained lidocaine for one side and a solution with no lidocaine for the contralateral side. No difference was found postoperatively in terms of pain level between the two sides. This study suggests that the lidocaine does not provide postoperative analgesia although the study size was small [*Level II Evidence*] [17].

In summary, wetting solutions have allowed more extensive liposuction whilst reducing associated blood loss. Table 1 summarises the estimated blood loss associated with the various wetting solutions. There still remains much debate on the use of superwet versus tumescent solution in liposuction. Rohrich et al. reviewed the literature on wetting solutions and recommended the use of the superwet technique. They found no evidence for any benefit of using tumescent solutions in terms of safety or efficacy. The superwet technique had comparable blood loss to tumescent liposuction but without the risks of fluid overload and congestive heart failure [14]. Perry et al. have recommended that no lidocaine is required in patients undergoing the procedure under general anaesthesia [17].

Liposuction Techniques

Fischer and Fischer were the first to use suction for aspiration of fat [2]. Further advances in lipoplasty have come from the development of devices to assist in the fragmentation of fat to allow easier removal. A survey of ASAPS members revealed SAL to be the preferred method amongst 51% of respondents. Power- and ultrasound-assisted liposuction (PAL and UAL) were preferred by 23% and 21% respectively. Laser assisted lipoplasty (LAL) was only preferred by 4% of the respondents [18].

Table 1. Estimated blood loss using various wetting solutions [7]

Wetting Solution	Estimated blood loss as% of volume
Dry	20-45%
Wet	4-30%
Superwet	1%
Tumescent	1%

Suction Assisted Lipoplasty (SAL)

SAL relies on the mechanical motion of the cannula to disrupt and avulse adipocytes, which are then aspirated via tubing connected to suction. The suction pressure was classically described to be one atmosphere (760 mmHg), although these days the pressure varies from about 300-600 mmHg [19]. SAL remains the most commonly used technique and is often the benchmark against which other techniques are compared.

Syringe Aspiration

In 1986, Fournier described the use of syringes for fat aspiration [20]. The same year, Toledo began using syringe liposuction combined with fat grafting, which he termed 'syringe liposculpture' [21]. These and other authors have presented their series but only a small number of comparative studies have been performed analysing syringe and suction liposuction. Lewis et al. compared syringe and suction pump aspiration in a small series of six patients. They reported less bruising and less blood loss with the use of the syringe for aspiration [*Level II Evidence*] [22]. This was confirmed by another small comparative study of ten patients [23]. The main advantages of the syringe technique are reported as accurate fat removal, precise quantification, less blood loss, less pain and preservation of adipocytes. The major disadvantage, however, is a significantly lengthened operative time [*Level II Evidence*] [23]. The negative pressure generated by various syringes appears to be primarily related to the volume aspirated and independent of the syringe calibre. Table 2 illustrates the negative pressure generated with varying amounts of aspiration. The negative pressure achieved with 60ml of aspiration is similar to that expected for a SAL device [*Level V Evidence*] [24]. The role of syringe aspiration of fat has recently seen a renaissance with the rising popularity of lipomodelling.

Table 2. Negative pressure generated using various syringe sizes [24]

Volume aspirated (ml)	Negative pressure generated (mmHg)	Negative pressure generated (atm)
1	-165	-0.21
3	-349	-0.45
10	-559	-0.735
30	-667	-0.877
60	-718	-0.944

Power Assisted Lipoplasty (PAL)

PAL refers to the use of a reciprocating cannula attached to a suction source. The MicroAire device, approved by the FDA in 1998, has a cannula that reciprocates at 2000-4000 cpm with a two millimetre stroke [25]. Fodor and Vogt performed a pilot study in thirty patients comparing PAL with traditional SAL [26]. Patients served as their own controls having one side treated with PAL and the other with SAL. There was no difference between sides in terms of pain, oedema or ecchymosis but PAL was reportedly better at breaking up fibrous fatty areas and superficial layer liposuction. The other main advantage of PAL was reduced surgeon fatigue. Disadvantages included expense and some degree of surgeon discomfort due to vibration of the instrument [*Level II Evidence*] [25,26].

Katz et al. performed a comparative study of PAL versus SAL in 21 patients under tumescent anaesthesia, patients again serving as their own controls. The mean aspirated volume was 1400ml and the amounts of supernatant and infranatant aspirate were similar in both groups. Compared with SAL, PAL was carried out 35% quicker and was associated with 45% less intraoperative and 38% less postoperative pain. Ecchymosis and oedema were also 37% and 32% less on the PAL side respectively [*Level II Evidence*]. No complications were reported in this series [27].

Scuderi et al. confirmed these findings in their series of fifteen patients comparing PAL, SAL, and UAL [28]. PAL reduced operative times by almost 50% compared to UAL and 25% compared to SAL. PAL and UAL had significantly lower mean haemoglobin concentrations in the lipoaspirate compared with SAL, suggesting it produced less trauma. No differences were found in terms of aesthetic outcome between the three methods of liposuction. The investigators also noted more surgeon distress with the PAL device due to the vibration of the reciprocating cannula [*Level II Evidence*] [28]. A further study of fifteen cases confirmed the superiority (in terms of total amount of fat removed) of PAL over SAL in the treatment of more fibrous areas [*Level II Evidence*] [29].

Ultrasound Assisted Lipoplasty (UAL)

The use of ultrasound in body contouring is often credited to Zocchi in 1980s. In his 1992 paper entitled 'ultrasonic liposculpting' he described the theory underlying the use of ultrasound and the technique of UAL [30]. The potential benefits of UAL as described by Zocchi are summarised in Table 3 [30].

The fragmentation of fat using ultrasound is thought to occur by three main mechanisms: cavitation, thermal effects and mechanical effects [30]. The first-generation devices used solid blunt probes of four to six millimetre diameter to deliver a continuous ultrasound. This caused fragmentation of fat that subsequently required aspiration. Second-generation devices, such as the Lysonix (Lysonix Inc.), allow simultaneous ultrasound delivery and aspiration. Its probes are about five millimetres in diameter with only a two millimetre lumen for aspiration, resulting in a significant amount of time required for aspiration. The ultrasound delivery is also continuous and the necessary incisions are in the region of 1cm to allow for instrumentation and the use of skin protectors [31].

Although UAL has been described for some time there were few who used it in view of the high complication rates reported with early devices. There have been numerous papers in the literature reporting a range of complications.

Zocchi published his initial series of 280 patients treating over 1000 areas. He reported no complications apart from incision site skin distress prior to the introduction of skin port protectors [*Level IV Evidence*] [30].

Table 3. The potential benefits of UAL [30]

Potential Benefits of Ultrasound Assisted Liposuction
Selective destruction of fat whilst respecting surrounding tissues
Smoother/more regular skin surfaces, caused by elimination of the fluid part of the adipose tissue whilst retaining higher density structures (adipocyte wall, intracellular substance and thick cellular residue)
Potential for skin tightening by stimulation of the deep dermis
Potential to treat cellulite and peau d'orange skin
Reduced physical exertion for the surgeon

Maxwell and Gingrass reported their experience with some first and second-generation UAL devices in 250 patients. In this series, the average volume aspirated was 3940ml with an average fat content of the aspirate of 63%. There were three cases (1.2%) of significant abdominal skin necrosis and 28 seromas (11.2%) [*Level IV Evidence*]. They preferred a deeper plane of UAL to Zocchi who described superficial use to stimulate the dermis [32].

In 1998, Fodor et al. performed a comparative study of UAL with SAL in 100 patients. Patients had UAL performed on one side and SAL on the contralateral side using a superwet infiltration. The supernatant fat averaged 75% of the total volume of aspirate in UAL but was not stated for SAL. The lipocrits from the infranatant aspirate were found to be less than one percent in both SAL and UAL, signifying a very low blood content within the aspirate. No significant differences were found in terms of satisfaction, ecchymosis and swelling. Relative procedure times were not recorded. The authors did not observe any significant advantage in terms of skin retraction using the UAL. No complications were reported in either group [*Level II Evidence*] [33].

Scuderi et al. compared UAL with SAL and PAL in 45 patients, each treatment group comprising of fifteen patients. The UAL group was found to have a significantly higher supernatant fat content than in PAL and SAL (eighty percent compared with fifty percent). The mean triglyceride concentration in the lipoaspirate in the UAL was also much higher than PAL and SAL, thought to be due to the specific adipocyte disruption caused by sonication. The aesthetic outcome was similar amongst the three treatment groups, but both the cost and the operative time of UAL was significantly greater than PAL and SAL [*Level II Evidence*] [28].

A large series of 660 patients undergoing UAL reported a complication rate of 1.8%, the main complications being two episodes of hypotension, three seromas, three cases of contact dermatitis and one haemorrhage [*Level IV Evidence*] [34]. In the large series of various techniques by Triana et al. there was a significantly higher rate of both seromas and skin necrosis following UAL than either SAL or LAL [*Level IV Evidence*] [8]. UAL has also been compared to surgical lipectomy in a study of forty patients (with half undergoing each intervention) demonstrating that UAL took almost double the operative time but was associated with a five times shorter hospital stay. The surgical lipectomy group had no complications, whereas the UAL group, experienced ecchymosis (80%), orthostatic

hypotension (75%), cellulitis (75%), and epidermal loss in a small area (10%) [*Level II Evidence*] [35]. Although the sample size is small (n=20), the high prevalence of cellulitis as a complication in the UAL group is striking.

The evidence for the first- and second-generation UAL devices reveals variable complication rates. The main comparative trials have failed to show any significant benefit of UAL over SAL in terms of aesthetic outcomes [*Level II Evidence*] [28,33]. Renewed interest in UAL has been stimulated by the production of a new generation of devices.

Vibration Amplification of Sound Energy at Resonance (VASER)

The current third generation ultrasound devices, such as the VASER (Vibration Amplification of Sound Energy at Resonance), differs from earlier devices in a number of ways: VASER uses 2.9-3.7mm solid probes with grooves near the tip, which transfer some ultrasound energy to adjacent areas; ultrasound energy delivery can be pulsed rather than continuous, reducing heat production; and, according to some data, the VASER probe may be more effective at fragmentation and emulsification at half the energy settings of earlier UAL devices (Figure 1) [31,36]. The VASER requires an alternative device for the aspiration of the fat.

Jewell et al. first reported a pilot study of 77 patients undergoing VASER lipoplasty in 2002. They reported that the supernatant fat exceeded 80% of the total volume in all their cases and no complications [*Level IV Evidence*] [36]. In 2004, Fodor et al. confirmed the safety and efficacy of the VASER device in 400 patients [*Level IV Evidence*] [37].

A multicentre, prospective, randomised, single blind controlled trial comprising twenty females compared VASER and SAL, showing that VASER was associated with significantly less blood loss and better skin retraction. However no difference was detected at follow-up in terms of patient and surgeon satisfaction [*Level I Evidence*] [38].

A comparative study of lipoplasty aspirates from SAL and a third generation UAL revealed that the SAL aspirate had a 7.5 times higher haemoglobin content and a 6.5 times higher haematocrit. The study concluded that the third generation UAL device was associated with significantly less blood loss than SAL [*Level III Evidence*] [39].

Hoyos has refined the use of VASER in liposculpture with an approach referred to as 'VASER assisted high definition liposculpture' [40]. This builds on the Mentz technique of abdominal etching to produce the appearance of highly developed musculature (Figure 2) [41]. Hoyos et al. published a series of 306 patients undergoing high definition VASER from 2005 to 2007. They noted that 84% of their 257 were satisfied with their results. The main complications included: seroma (6.5%); port site burns (2.9%), prolonged swelling (1.6%), pigmentary changes (0.65%); and, cellulitis (0.65%) [*Level IV Evidence*]. [40] The reported seroma rate in this series was higher than described by Jewell et al. (of zero) but this was attributed to superficial layer liposuction performed by Hoyos [36]. This seroma rate was significantly lower than other UAL devices [*Level IV Evidence*]. The VASER, due to the lower energy used, did not produce any distant necrosis or skin necrosis unlike the early generation UAL devices.

Laser Assisted Liposuction (LAL)

Laser assisted liposuction (LAL) relies on the principle of selective photothermolysis to target specific chromophores at certain wavelengths [42]. The theoretical mechanisms of action and benefits for laser lipolysis are summarised in Table 4 [42].

Figure 1. Illustration of 3.7mm and 2.9mm VASER cannulas.

Figure 2. VASER assisted high definition liposculpture used to produce abdominal etching. Images courtesy of Dr Ravi Jain, Riverbanks Clinic, Harpenden.

The most commonly used laser liposuction devices are Neodymium:Yttrium Aluminium Garnet (Nd:YAG) lasers with a wavelength of 1064 nm. Use of the sequential 1064/1320nm Nd:YAG laser [43] and diode lasers of varying wavelengths [44,45] have also been reported.

Table 4. The mechanisms and benefits of LAL [42]

Liquefaction of adipocytes due to photothermal injury
Disruption of adipocytes assisting suctioning
Thermal energy resulting in improved haemostasis
Small access incisions typically of approximately 2mm

1064nm Nd:YAG LAL

In 2002, Badin et al. presented the first clinical series of 245 patients using the 1064nm Nd:YAG LAL. Reported benefits included skin retraction, reduced swelling and good contouring, and the authors recommended LAL in circumstances where conventional liposuction techniques could leave undesirable skin redundancy. The main disadvantages were the cost of the device, learning curve and increased operative time. They reported no complications in their series [*Level IV Evidence*] [46]. Fakhouri et al. have reviewed and summarised a number of case series reporting the use of 1064nm lasers in treating various areas [43].

In 2006, Prado et al. performed a prospective, randomised, double-blind controlled trial comparing SAL and LAL. They recruited 25 patients who were randomly assigned to undergo SAL on one side of the body and LAL on the other side. There were no reported complications in either group. No significant differences in cosmetic outcome were found between SAL and LAL using an objective grading system. Overall, patients reported more pain following SAL. LAL resulted in significantly lower lipocrits when compared to SAL. Histologically LAL resulted in ninety percent disruption of adipocyte architecture and rupture of the nuclear cellular membrane, whereas SAL resulted in 90% preservation of the adipocyte architecture with intact cellular membranes [*Level I Evidence*] [47].

Skin tightening is considered one of the main benefits of LAL. A large series compared a variety of liposuction techniques over a 25-year period, finding that LAL resulted in better skin retraction in areas such as the axillae, submental region and inner thighs. This effect was better than tumescent liposuction alone but was not significantly different from UAL. The authors did not describe how they measured skin retraction and it may have been a subjective assessment. They did not comment on the duration of these effects either [*Level IV Evidence*] [8].

Sequential 1064/1320nm Nd:YAG LAL

Histological and laboratory studies have shown that the 1320nm wavelength laser targets collagen (dermal and subcutaneous) and collagen-bound water more effectively than the 1064nm wavelength [*Level V Evidence*] [48]. Therefore, the 1320nm wavelength may be more efficient in fat disruption and result in better skin contraction [*Level V Evidence*] [49].

Woodhall et al. conducted a comparative study of the 1064 nm, 1320nm and combined 1064/1320nm Nd:YAG lasers. The first part of the study revealed no difference in fat reduction or skin retraction when comparing the 1064nm laser to tumescent liposuction alone in eight patients. The second study of ten patients showed no difference when comparing the 1064nm and 1032nm lasers. The third study, in which twenty patients underwent treatment with the combined 1064/1320nm multiplex laser, reported improvement in skin laxity when compared to the individual wavelength lasers. Thermal burns were reported in two patients (ten percent) using the multiplex device [*Level II Evidence*] [50].

A small series using a laser device with sequential firing of 1064 and 1320nm wavelengths demonstrated an average of 22% and 17% skin shrinkage respectively after one and three months [*Level IV Evidence*] [51]. This study comprised of only five patients but used tattoo markings to measure subsequent skin retraction accurately. A further study by DiBernardo on ten patients comparing SAL and LAL in a randomised split abdomen study revealed minimal difference between the two techniques at one month. At three months, however, a 62% improvement in skin tightening (again measured in terms of skin tightening) was noted on the side of the abdomen treated with LAL compared to only five percent on the SAL side [*Level II Evidence*] [52].

Diode LAL

Neira has described the technique of a low-level laser liposuction, which he has called the Neira 4L technique. This procedure uses a 635nm diode laser applied externally to the treatment areas for periods of six to twelve minutes. This low level laser causes liquefaction of the fat, which is then aspirated using SAL. Neira and coworkers reported a series of 700 patients in whom the average aspirate was five litres. They reported a patient satisfaction rate of 93% and a seroma rate of 40%. Other complications included asymmetries (3%), haematomas, bruising (5%), and infection (0.3%) [*Level IV Evidence*] [53].

The efficacy of 635nm diode low-level laser without liposuction has been investigated as a non-invasive method of body contouring. In a double-blind, randomised placebo-controlled trial, 67 patients underwent thrice weekly treatment using laser or placebo for two weeks. Measurements were taken of the waists, hips and thighs before the start of treatment and then at one, two and four weeks after starting treatment. Their results showed a statistically significant reduction in the measurements at two and four weeks compared with those at baseline in the treatment group but not the placebo group. However, some relapse was evident in hip measurements from two to four weeks suggesting that the effect could have been transient (Figure 3). Longer term follow-up would be needed to assess whether the benefits were maintained in the long-term [*Level I Evidence*] [54].

The 980nm diode laser has been used for lipolysis in view of its continuous wave emission and high power settings making it useful for large areas that require high cumulative energy. The use of 924nm and 975nm diode devices has also been reported. These are primarily small case series with no high level evidence available for these devices [43].

Figure 3. Circumference measurements of the waist (top) and hip (bottom) at each evaluation point for all participants (n=67). Modified from Jackson [54].

In summary, although numerous case series address the safety and efficacy of the 1064nm Nd:YAG laser, the only comparative study is that of Prado et al., showing no difference in aesthetic outcome between LAL and SAL [*Level I Evidence*] [47]. A number of case series with other lasers, such as the diode and 1064/1320nm multiplex, indicate some benefits in terms of skin retraction. A small randomised controlled trial showed short-term benefit of a diode laser on skin retraction [*Level I Evidence*] [54]. No long-term studies are available to assess the longevity of skin retraction. Some authors with vast experience of liposuction have reported little benefit of laser-assisted methods over tumescent suction liposuction techniques [*Level V Evidence*] [55].

THE FUTURE OF LIPOLYSIS AND BODY CONTOURING

There are continual developments in the field of body contouring. A few recent developments include water- and radiofrequency-assisted liposuction.

Water Assisted Lipoplasty (WAL)

The WAL device uses a dual-purpose cannula that produces a fan-shaped jet of tumescent infiltrate whilst simultaneously suctioning the instilled fluid and aspirated fat. The infiltration process comprises of two phases using different solutions. The first is preinfiltration with tumescent solution to produce anaesthesia and vasoconstriction in the treatment area. The second phase is simultaneous irrigation and aspiration using an infiltration solution with a lower local anaesthetic concentration than used in the first phase. The benefits of this technique include the use of a water jet to loosen adipocytes whilst preserving surrounding structures such as nerves and vessels [56]. Stutz et al. demonstrated histologically and immunohistologically in thirty lipoedema patients undergoing WAL that adipocytes largely survived and there was no evidence of damage to lymphatics [*Level V Evidence*] [57]. This has led to it being considered for fat harvesting in lipomodelling. A case series exploring the safety and efficacy of WAL in 41 consecutive patients for body

contouring and lipoharvesting found it to be safe with minimal blood loss and lipocrits estimated at less than one percent. The investigators found ninety percent of adipocytes were viable using special staining techniques in five patients [*Level IV Evidence*] [58].

Araco et al. conducted a randomised trial comparing WAL and traditional liposuction. In their study of sixty patients (28 traditional vs. 32 WAL), those undergoing WAL had pain scores 4.8 times less than traditional liposuction, which was statistically significant. In the WAL group, 87% were pain free after four days compared to only 3.6% in the traditional group. The WAL group also had significantly less ecchymosis. There was no significant difference in aesthetic outcome between the two procedures [*Level I Evidence*] [59].

There remains little evidence in the literature for the use of WAL in body contouring and lipomodelling at present. The few small case series do, however, provide interesting results and highlight this as an interesting technology for further research.

Radiofrequency Assisted Liposuction (RFAL)

The radiofrequency assisted liposuction (RFAL) device comprises a bipolar radiofrequency (RF) probe in which an internal electrode is inserted into adipose tissue and an external electrode applied to the skin surface (Figure 4). The internal RF probe then emits RF current through a small conductive tip [60]. Potential benefits of RFAL are summarised in Table 5.

Figure 4. Radiofrequency assisted liposuction.

Table 5. The benefits of radiofrequency assisted liposuction [60]

The Benefits of Radiofrequency Assisted Liposuction
Faster treatment
Reduced tissue trauma
Improved safety
Uniform heating of skin and subcutaneous tissues
Potential for skin retraction

Paul and Mulholland presented their experience of the RFAL device in a series of twenty patients. Compared with a LAL device the time taken to heat a treatment zone was significantly faster and heat distribution was more uniform with RFAL. Histological analysis following RFAL revealed extensive destruction and coagulation of adipocytes and adipose tissue, along with coagulation of small to medium sized blood vessels and preservation of the subdermal plexus. There was also coagulation of deep, reticular dermal collagen suggesting

the potential for skin retraction. There were no reported complications of the treatment [*Level IV Evidence*] [60].

There have been a number of other case studies using the RFAL device in the literature. Blugerman et al. presented 23 patients with an average aspiration of 2404ml. The series demonstrated significant reductions in weight and circumference measurements at six weeks and three months follow up, and the authors commented on significant skin tightening following treatment. There were no reported complications in the series [*Level IV Evidence*] [61]. These findings have since been confirmed by Hurwitz et al. [*Level IV Evidence*] [62] and Ion et al. [*Level IV Evidence*] [63].

Theodorou et al. performed RFAL in 97 patients with an average aspiration of 1146 cc. They reported rates of major and minor complications of 6.25% and 8.3% respectively. The overall patient satisfaction was 82% for skin tightening and 85% for body contouring [*Level IV Evidence*] [64].

These initial series have shown some promising results, but no comparative studies or randomised clinical trials have been performed to date.

LARGE VOLUME LIPOSUCTION

Large volume liposuction has been defined as the removal of 5000ml or more of total aspirate (that is, fat plus re-aspirated infiltrated solutions) during a single procedure [15]. The literature does not provide clear evidence for the maximum safe volume of aspiration, but higher complication rates and death have been reported when larger volumes or more anatomical sites are treated [66,70].

Rohrich et al. reviewed over 200 patients undergoing aspirations exceeding five litres and gave recommendations for fluid resuscitation: when less than five litres is aspirated the maintenance fluid plus the volume of subcutaneous wetting solution is adequate resuscitation; whereas when more than five litres is aspirated, an additional 0.25ml of crystalloid for every 1ml of aspirate over five litres is given [*Level IV Evidence*] [14].

In 1999, Albin et al. reported a series of 181 patients undergoing liposuction of more than five litres. In this series, seven patients underwent aspiration of over twenty litres, of whom one had a deep venous thrombosis and one a pulmonary embolus [*Level IV Evidence*] [65]. In a larger series of 631 patients over twelve years, Commons reviewed patients undergoing liposuction of more than three litres. They highlighted the low complication rates in their patients and overall safety of large volume liposuction [*Level IV Evidence*] [66]. They also recommended overnight monitoring in such large volume liposuction patients. In 2008, Choudry et al. published their series of 62 patients undergoing large volume liposuction. They found five patients with symptomatic postoperative anaemia requiring blood transfusion and one patient with a haematoma requiring operative evacuation [*Level IV Evidence*] [67].

COMBINED LIPOSUCTION AND ABDOMINOPLASTY

The concept of liposuction combined with abdominoplasty has been around since the mid-1980's. There were a few reports of cases where combinations of procedures were

undertaken with varying degrees of skin resection from mini- to full-abdominoplasty. There were initial concerns regarding higher complications with combined procedures focussing on the viability of the abdominal skin flaps following liposuction [68]. Matarasso has described safe areas for combined lipoabdominoplasty based on the blood supply of the abdominal wall (Figure 5) [68,69]. An ASAPS survey explored the liposuction morbidity and mortality of its members. The survey found that the mortality rate associated with liposuction alone was 0.0021%. When liposuction was combined with abdominoplasty, however, the mortality rate rose to 0.0305%, which was fourteen times more than liposuction alone [70].

There have been a number of studies exploring the safety and efficacy of lipoabdominoplasty since that survey. Vila-Rovira described a series of 48 patients in whom extensive liposuction with minimal dissection abdominoplasty was performed. This method utilises the Avelar technique that uses liposuction of the upper and lower abdomen to allow the skin to be advanced without undermining the skin flaps. Minimal undermining creating a tunnel from the umbilicus to xiphoid whilst preserving the perforators and Scarpa's fascia is performed. In this series, complications included: seromas (ten percent); small areas of skin necrosis (ten percent); haematomas (two percent); cutaneous irregularities (twenty percent); secondary liposuction (ten percent); and scar revisions (ten percent) [Level IV Evidence] [71].

Heller et al. described a comparative study in which 114 patients underwent various body contouring procedures. They found that the lowest complication rate (at five percent) was in the liposuction only group. The traditional W-pattern and modified low transverse abdominoplasty procedures had overall complication rates of 42% and 17%, respectively. The combined lipoabdominoplasty group had a significantly lower complication rate of 9% [Level III Evidence] [72].

In 2010, Weiler et al. reported a series of 173 patients undergoing lipoabdominoplasty. In this series complications included partial dehiscence or skin necrosis (6.9%), infection (7.5%), seroma (3.4%), major fat necrosis (0.5%) and skin flap necrosis (1.1%). Systemic complications included deep venous thrombosis (2.8%) and pulmonary embolism (1.1%) [Level IV Evidence] [73].

Figure 5. Anatomic areas for safe suction in combined abdominoplasty-liposuction [68,69].

Most recently, a prospective outcome study of 360 patients treated with liposuction, lipoabdominoplasty or abdominoplasty was reported [*Evidence Level II*]. In this study, lipoabdominoplasty and abdominoplasty patients experienced significantly more pain and complications than liposuction alone. The complication rates were 3.7% for liposuction only, 21.9% for lipoabdominoplasty, and 15.4% for abdominoplasty alone. However the highest level of patient satisfaction (99.2%) was from the combined lipoabdominoplasty procedure. The lipoabdominoplasty group also reported the most improvement in quality of life, self-esteem and self-confidence [*Level II Evidence*] [74].

In summary, combined liposuction and abdominoplasty carries a higher complication rate but the patient reported outcomes in this group are significantly better than liposuction alone.

CONCLUSION

There has been a huge increase in demand for liposuction, currently making it the most popular cosmetic surgical procedure globally. Early concerns about the safety of the procedure have been alleviated by the use of wetting fluids and the associated reduction in blood loss, but this has introduced new issues with fluid balance. Safety issues were also raised when large volume liposuction was performed but recommendations and guidelines have been reported to reduce adverse events in these cases. There have been considerable developments technologically in the production of devices to assist with liposuction. We have seen that there are, however, only a very small handful of high-level evidence based studies available in the field of liposuction. The majority of the literature comprises case series' of variable size based on personal experience. There is a need for more randomised controlled trials and comparative studies in liposuction to help elucidate the effectiveness of new emerging technologies.

Chapter 38

BOTULINUM TOXIN

Darren J. McKeown*

Aesthetic Medicine Institute, Glasgow, UK

KEY POINTS

Botulinum toxins exert their effect by blocking the action of acetylcholine, a neurotransmitter involved in neuromuscular and neuroglandular signalling.

Dosage units of different brands of botulinum toxin type A are not always equivalent. Botox and Xeomin have a roughly 1:1 dose conversion rate whereas Botox:Dysport conversion ratios of 1:2 to 1:5 have been suggested.

Using a Botox:Dysport conversion ratio of 1:2.5, Dysport appears to last longer, produce greater reduction of dynamic lateral canthal rhytids, be associated with greater patient satisfaction and be more cost-effective. Dysport appears to have a greater range of diffusion, which may be an advantage or disadvantage.

Reconstituted products remain effective for at least several weeks if refrigerated, contrary to manufacturer's guidance.

There is no evidence of an adverse effect of prolonged regular use of botulinum toxin for control of dynamic rhytids, although no very long-term studies exist.

INTRODUCTION

At no time in the history of aesthetic practice can a drug be said to have made more impact than botulinum toxin. Since Jean and Alastair Carruthers described the aesthetic benefits of this new class of drug in 1987, the use of botulinum toxin products has expanded year on year to become the most popular aesthetic treatment in both the UK and the USA, with the use of these drugs now dominating the management of many signs of ageing that were traditionally considered a surgical problem.

* Corresponding Author's Email: drdarrenmckeown@gmail.com.

Botulinum toxins have been more significant to aesthetic practice than simply an extra tool for the practitioner. This class of drugs has paved the way for the increasing trend for non-surgical treatment and has shifted the goals of aesthetic practice from ‘cure’ to ‘prevention’.

Whilst botulinum toxins are best utilised for rejuvenation of the upper face, they also play a role in the lower face and neck, particularly in combination with other non-surgical techniques such as soft tissue fillers, chemical peels, lasers and other light devices for skin rejuvenation. These non-surgical techniques in combination now form a critical part of modern aesthetic practice.

MECHANISM OF ACTION

Botulinum toxin is a potent neurotoxin produced by *Clostridium botulinum*. There are seven known serotypes [1], each produced by a different strain of the bacterium and labelled A to G. The human body is susceptible to five of these subtypes – except for types C and D [1]. Only types A and B are currently available as commercial drug preparations and in aesthetic practice only type A has proven to be clinically useful [1].

Botulinum toxins exert their effect by blocking the action of acetylcholine, a neurotransmitter involved in neuromuscular and neuroglandular signalling. Depending on the serotype, the toxin binds selectively and irreversibly to a particular surface protein on the presynaptic nerve terminal that subsequently prevents release of acetylcholine into the synaptic cleft.

Type A botulinum toxin consists of one heavy (147kD) and one light chain (52kD) [1]. The heavy chain gains access to the cell by binding to its membrane whereas the light chain cleaves synaptosomal associated protein-25 (SNAP-25) on the membrane’s cytosolic surface. SNAP-25 is normally responsible for allowing intracellular acetylcholine containing vesicles in the nerve terminal to fuse with the cell membrane and discharge their contents into the synaptic cleft[1]. Since the binding of botulinum toxin type A to SNAP-25 is an irreversible process, cell signalling can only recommence when the nerve endings sprout new nerve terminals, a process that takes several months to occur and accounts for the prolonged results achieved after botulinum toxin treatment.

ANTIDOTE

An antidote is available for botulinum toxin but it must be administered within four hours to be effective. This is clinically impractical as it takes several days for any adverse events to be observed.

NOMENCLATURE

There are currently three commercial preparations of botulinum toxin type A available in the UK and USA. The proprietary and non-proprietary naming of the different preparations is

complex, with different proprietary and non-proprietary names being used on either side of the Atlantic, and recent changes in the proprietary labelling of botulinum toxin products in the USA and non-proprietary labelling in the UK add to the potential for confusion.

The first botulinum toxin type A to be licensed in the United States was manufactured by Allergan and known by the proprietary name of botulinum toxin A and the non-proprietary name Botox. It was approved in 1989 for the treatment of strabismus, blepharospasm and hemifacial spasm and was later granted a license by the USA Food and Drug Administration (FDA) for the treatment of moderate to severe glabellar rhytids under the separate non-proprietary name of Botox Cosmetic in 2002.

In the UK, Botox was licensed for medical use in 1994 and subsequently granted a cosmetic license under the non-proprietary name of Vistabel in 2006. In November 2011, however, the UK Medicines and Healthcare products Regulatory Agency (MHRA) granted Botox a license for treating glabellar rhytids and Vistabel was subsequently withdrawn from the market. Now, all Allergan botulinum toxin products in the UK are simply known as Botox.

Dysport was originally licensed in the UK for the treatment of blepharospasm and hemifacial spasm in 1990. Although the drug was widely used for cosmetic indications from that time, it was not until 2009 that it was granted a cosmetic license under the separate name of Azzalure. In the same year, Dysport was licensed in the US for the treatment of cervical dystonias and glabellar rhytids under the trade name of Reloxin.

Dysport and Botox have significantly different dosing requirements and injection techniques. To avoid confusion, when Dysport was licensed in America the FDA changed the proprietary name of Botox from botulinum toxin type A to onabotulinumtoxinA and Dysport was given the proprietary name of abobotulinumtoxinA. In the UK however, the proprietary name for both preparations remains botulinum toxin type A.

Most recently, Xeomin, which has a similar dosing regimen to Botox, was granted a license for treatment of blepharospasm in the UK in 2007. The same drug was also granted a license to treat moderate to severe glabellar rhytids under the separate name of BoCouture in the UK in 2010. The FDA approved Xeomin in 2010 for the treatment of glabellar rhytids, cervical dystonia and blepharospasm all under the one name. In the US, the proprietary name for this product is incobotulinumtoxinA.

Where a cosmetic license has been granted to a botulinum toxin type A product – both in the UK and in the USA – the license at the time of writing only includes the treatment of moderate to severe glabellar rhytids. Although other indications are regularly treated, this is on a ‘off label’ basis and patients must be consented as such prior to treatment.

DOSE CONVERSION BETWEEN BRANDS

The dosage units of different brands of botulinum toxin type A products are not always equivalent and care must be taken when converting between them. Despite earlier reports otherwise, Botox and Xeomin have a roughly 1:1 dose conversation rate and as a general rule, doses can be used interchangeably [2].

Dysport, however, has a very different dosing regimen, and conversion ratios of Botox:Dysport from 1:2 to 1:5 have been suggested. In clinical practice a conversion ratio of 1:2.5 to 1:3 appears to be optimal (Wohlfarth 2001).

CLINICAL EFFICACY COMPARISON OF BOTULINUM TOXIN TYPE A BRANDS

There is much debate over which brand of botulinum toxin is superior in terms of efficacy of wrinkle reduction and longevity of results. Much of the literature compares Botox with Dysport since they have been available the longest. Early work comparing Botox and Dysport suggested that Botox was superior in terms of duration of effect [3,4]. However, these studies used relatively low doses of both drugs that were out of keeping with clinical practice, whilst more recent studies using higher doses of both drugs indicate that the relationship between the two is not simple.

In a study comparing Botox 30U and Dysport 75U injected at five injection points in the glabella (i.e., a conversion ratio of 1:2.5), both drugs had similar efficacy in terms of wrinkle reduction and duration of effect. When the conversion ratio was increased to 1:4U, comparing 64U of Botox with 256U of Dysport, Dysport was significantly more effective [5].

Nestor compared 10U Botox with 25U Dysport on contralateral sides of the same forehead (i.e., a conversion ratio of 1:2.5). In this study, Dysport lasted significantly longer than Botox [6]. At the lateral canthus, Nettar compared 10U of Botox on one side to 30U of Dysport on the other side, finding that Dysport resulted in a significantly greater reduction in dynamic rhytids and greater patient satisfaction[7]. There is also some evidence that Dysport has a more rapid onset of action than Botox and may be more cost effective [2,8].

ZONE OF DIFFUSION

There is evidence to suggest that Dysport has a greater zone of diffusion around injection points than the other two brands of botulinum toxin. This can be used at the surgeon's discretion to assist in achieving aesthetic objectives. For example, a diffuse effect may be desirable when treating a broad, flat muscle such as frontalis, whereas a more localised effect is preferable when treating smaller muscles. In the latter instance Botox may be the preferable brand [9].

RECONSTITUTION AND STORAGE

As a general rule, manufacturers recommended reconstitution and storage guidelines are not backed by scientific evidence and are excessively restrictive. Manufacturers of Botox, Dysport and Xeomin each recommend their product should be used within 24 hours of reconstitution, although the literature suggests that the products remain stable and efficacious for several weeks or months after reconstitution provided they are maintained in refrigerated conditions [10-12].

The volume of saline used for reconstitution can safely be varied depending on the preferences of the practitioner. Clinically useful reconstitution guidelines for aesthetic indications are summarised in Table 1.

It is desirable to keep dilution low and drug concentration high to reduce the volume of injectate and minimise immediate unsightly subcutaneous swelling, allowing patients to resume their daily activities straight away. Nonetheless, the use of higher dilution volumes is safe, does not impact the effectiveness of the drug and does not increase the incidence of diffusion related complications [13].

Concern has been expressed that the foaming resulting from excessively rapid injection of saline during botulinum toxin reconstitution could cause denaturation of the protein. A randomised clinical trial has shown these concerns to be unjustified [14].

CONTRAINDICATIONS TO TREATMENT

Botulinum toxin injections should not be performed at the site of an active infection. Patients should not be treated if they are currently pregnant or nursing a child, although there have been no reports of teratogenicity in cases of inadvertent treatment under such circumstances. Caution should be exerted in treating patients who have peripheral nerve disorders or neuromuscular disorders such as myasthenia gravis or Eaton-Lambert syndrome. Aminoglycosides appear to have an acetylcholine blocking action that may potentiate the effects of botulinum toxin and so caution should be exerted in patients who are concurrently taking these antibiotics [15].

INJECTION TECHNIQUE

Botulinum toxins should be injected using either a 30G or 32G insulin syringe in an effort to minimise discomfort and to allow the most accurate control of dosing. Injections are placed either subcutaneously on the surface of the muscle or within the muscle belly. There is no need to touch periosteum and inject on withdrawal as has previously been suggested.

PAIN MANAGEMENT

To meet the high expectations of aesthetic patients, treatment with botulinum toxin needs to be quick, easy and pain-free, or at least associated with minimal discomfort. A number of techniques have been described to assist with this objective.

The use of topical anaesthetic cream [16] and prior skin cooling with ice [17] can reduce the pain associated with botulinum toxin injections. In practice however, these steps are rarely undertaken as it makes the procedure more time-consuming and inconvenient and are usually only accepted by the most pain intolerant patients.

Reconstitution of botulinum toxin with preserved saline rather than the manufacturer's recommended non-preserved saline causes significantly less pain and is a useful strategy to make the experience more comfortable without any additional inconvenience [18].

Table 1. Reconstitution guidelines for aesthetic use of botulinum toxins

Drug	Units per vial	Reconstitution volume	Units per 0.1ml
Botox / Xeomin	100	2.50ml	4
Dysport	300	1.50ml	20
Dysport	125	0.63ml	20

CLINICAL APPLICATION OF BOTULINUM TOXIN

There are three basic principles of muscular physiology relevant to treatment with botulinum toxin. Consideration of these key principles, and their aesthetic implications, is useful when planning a series of injections.

1. There is an inverse relationship between muscle tension and length. A muscle treated with botulinum toxin becomes relaxed and so lengthens perpendicular to the direction of the overlying rhytids. This can be clinically troublesome, for example when treating the horizontal rhytids in the forehead: after treatment, the vertical length of the muscle is increased, resulting in an apparent lengthening of the forehead and depression of the brow.
2. Each muscle of facial expression affects the appearance of the overlying skin. When a muscle of facial expression is paralysed, this will have the opposite effect on the position of the overlying skin. For example, the corrugator supercilli depresses the brow medially upon contraction. When this muscle is treated with botulinum toxin the result is lateral deviation of the brow.
3. When a section of muscle is paralysed, the surrounding musculature will often overact in a compensatory mechanism. This can be especially relevant when the central two thirds of the frontalis are treated, preserving the lateral one-sixth on either side. Compensatory overactivity of the untreated area will result in unnatural flaring of the outer third of the brow.

By anticipating these unwanted effects it is possible to preempt and avoid them, maximising the aesthetic outcome of the treatment.

TREATMENT AREAS

Treatment with botulinum toxin is best considered in terms of individual treatment areas. These can be broadly grouped into those of the upper face, the lower face and the neck. As a general rule, treatment of the upper face achieves the most consistent results and practice is best supported by evidence. In the lower face, treatment outcomes are less predictable and the evidence is less complete.

Upper Face

Glabella

As the only facial area licensed for the cosmetic use of botulinum toxins at the present time, there exists the most published evidence relating to treatment of the glabella.

Anatomical Injection Sites

The glabella muscle complex consists of the procerus muscle centrally and the corrugator supercilli muscles laterally on either side. In addition, depressor supercilli may contribute to the dynamics of this region. The standard injection pattern for treating the glabella includes five injection points: one central injection in procerus and two laterally on either side in the corrugators (Figure 1a) [15]. Whilst this is usually sufficient, in some – particularly male – patients with a broader and bulkier muscle, more injections may be necessary [15] (Figure 1b).

Procerus is a small pyramidal shaped muscle that originates from the nasal bones and superior border of the upper lateral cartilages and inserts into the forehead skin between the eyebrows. It is a depressor of the medial forehead. The bulk of the muscle is easy to palpate and a single injection at the level of the nasion usually treats it adequately [15].

The Botox product insert pack recommends two injection sites in either corrugator supercilli muscle. The medial injection is recommended at the level of the inner canthus one centimetre above the eyebrow and the lateral injection point is recommended 1cm above the eyebrow, just medial to the mid-pupillary line. These anatomical landmarks do not correspond to the underlying anatomy, however. Guyuron has shown in a cadaver study that the origin of the corrugator supercilli lies approximately two millimetres lateral to the nasion at the level of the orbital rim [19]. Injection one centimetre above the eyebrow is likely to miss the targeted muscle and result in overtreatment of the inferior and central portion of the frontalis. This results in an unattractively depressed medial brow.

At the central origin, corrugator supercilli lies deep to the frontalis, adherent to the underlying periosteum. As the muscle travels laterally towards its insertion in the skin above the medial third of the brow it becomes progressively more superficial. Anatomically precise injection therefore requires a two plane injection technique with a deep injection medially and a more superficial injection laterally above the medial third of the brow [20] (Figure 2c).

Figure 1. Left: Standard injection pattern of botulinum toxin for treating the glabella; Middle: Injection pattern for patients with bulkier muscle; Right: planes for botulinum toxin injections. Doses are for Botox.

Depressor supercilli is a contentious muscle. Whilst some have argued that it merely represents the superomedial aspect of the orbicularis oculi muscle, a cadaver study reports it as a distinct muscle originating from the superior process of the maxilla approximately ten millimetres above the medial canthus and inserting to the skin fourteen millimetres superior to the canthus [21]. It is rarely of clinical importance the first time the glabella is treated but can become clinically relevant later on when the patient is still able to depress the brow despite other muscles of the glabellar complex being paralysed. In such situations, a small dose directed into depressor supercilli will cure this.

Optimal Dosage

The licensed dose of Botox and Xeomin to treat the glabella is 20U, and that of Dysport is 50U. However the optimal dose to treat this region has been the subject of a number of studies. Carruthers and colleagues carried out a multicentre, double-blind placebo controlled trial of 20U of Botox injected at five injection points in patients with moderate to severe glabellar rhytids. Patients experienced a reduction in the appearance of rhytids lasting up to 120 days. This study was the basis for Botox receiving its cosmetic license in the USA [22].

The same group subsequently published a dose ranging study comparing the efficacy of four doses of Botox in the treatment of the glabella in female patients [23], comparing 10U, 20U, 30U and 40U of Botox using five injection points in the glabella. Patients who received the three higher doses had a significantly greater response compared with the group who received 10U. There were no statistically significant differences between the 20U, 30U and 40U groups at any time, indicating that higher doses do not result in more prolonged effects [23]. This may be due to saturation of the nerve terminals at 20U, beyond which additional product has no additional benefit.

Carruthers also completed a dose ranging study comparing 20U, 40U, 60U and 80U in male patients, again finding that the higher three doses (40U, 60U and 80U) were significantly more effective than 20U. The investigators therefore recommended a starting dose of 40-80U in male patients [24].

Brandt and colleagues carried out a randomised, placebo controlled trial of 50U of Dysport. They found an 89.5% response rate in the treatment group compared with a 7.5% response rate in the placebo group, indicating that 50U Dysport is an effective dose in a majority of patients. Ascher and colleagues compared three doses of Dysport for the treatment of glabellar rhytids: 25U, 50U and 75U injected at five sites in the glabella [25]. They found that both 50U and 75U provided significant improvements in the appearance of glabellar rhytids for up to three months and was superior to 25U.

Horizontal Forehead Rhytids

Treatment of horizontal forehead rhytids with botulinum toxin is one of the most technically challenging areas and is associated with the greatest risk of patient dissatisfaction.

Anatomy of Injections

The frontalis is a broad, flat muscle overlying the frontal bone. It has no bony attachments. Inferiorly its medial fibres are continuous with procerus, intermediate fibres interdigitate with corrugator supercilli and orbicularis oculi, and lateral fibres interdigitate with orbicularis oculi. Superiorly it is continuous with the galea aponeurotica below the coronal suture. The medial borders of the muscle on either side are continuous for a variable

distance above the nasion before becoming separated by a portion of galea. Its extent is easy to determine simply by asking the patient to elevate his or her eyebrows and observing the wrinkling pattern in the overlying skin (Figure 2).

Before treating frontalis it is vital to consider whether it is actually aesthetically desirable to do so. The frontalis is the only brow elevator and paralysing it will almost always produce some brow ptosis [26]. The surgeon must anticipate the extent of brow ptosis and whether it will be aesthetically acceptable prior to undertaking treatment. In general, younger patients with minimal skin excess of the forehead and upper eyelid will suffer little or no significant ptosis, and the frontalis may safely be treated in its entirety. In contrast, older patients with a hyperfunctional frontalis (compensated upper lid excess/brow ptosis) will always suffer from clinically significant brow ptosis and should not be treated. Between these spectra lie a majority of patients in whom it may be safe to treat a portion of the frontalis but not the entire muscle.

In patients where there is concern regarding the degree of brow ptosis it is possible to treat only a section of the frontalis. Some have suggested treating only the central two thirds of the muscle, sparing the regions lateral to the mid-pupillary line on either side. In practice, however, this causes depression of the medial brow and flaring of the lateral brow, producing a very unnatural brow contour. When it is undesirable to paralyse the entire frontalis muscle the author prefers to inject its entire width, placing the injections higher up on the forehead (at least three to four centimetres above the eyebrow). This leaves an inferior band of functioning muscle that can support the brow. Although this leaves some rhytids above the eyebrows it is preferable to an unnatural brow contour. Whenever treating the forehead in this high-risk group of patients it is essential that the brow depressor muscles are treated simultaneously.

Injection sites should be placed along the entire width of the muscle, approximately two to three centimetres apart as far as the lateral extent of the horizontal forehead rhytids on either side. For most forehead sizes this will result in a row of four to six injection sites. If the patient has a tall forehead, more likely in male patients, then it may be necessary to carry out two separate rows of injections in order to achieve a satisfactory result. In some patients there may be no muscle in the centre of the forehead in which case there is no need to inject in this area (Figure 3).

Figure 2. The extent of frontalis can be determined by asking the patient to elevate their brows.

Figure 3. Injection pattern for treatment of frontalalis with botulinum toxin. a) Standard injection pattern; b) injection pattern in patients with a tall forehead; c) injection pattern for patients with frontalis divarication. All points represent injections of 2U Botox.

Dosage

There is a paucity of high quality data regarding the optimal dose of botulinum toxins for use in the forehead. Carruthers carried out a double-blind, randomised dose ranging study to investigate the optimal dosage of Botox to use in the forehead in female patients. Patients were randomised to receive 16U, 32U or 48U of Botox. Half of this dose was injected to the frontalalis (i.e., 8U, 16U and 24U respectively) and the other half injected into the brow depressors. They found significant dose-response trends, with greater wrinkle reduction and longer lasting results in the patients who received higher doses [27].

Ultimately, the total injection dose will vary depending on the size of the patient's forehead, the extent of the frontalalis muscle and the portion of the muscle that is desirable to paralyse. As a starting guide, each injection point should receive either 2U of Botox or 5-6U of Dysport.

Lateral Canthal Rhytids (Crows Feet)

Treatment of the lateral canthal rhytids with botulinum toxin is one of the earliest described indications of the drug and can provide some of the most satisfying results.

Anatomy of Injections

Orbicularis oculi is a sphincteric muscle responsible for closing the eyelids. It originates medially near the inner canthus and its fibres pass laterally across the eyelids with the lateral portion of the muscle extending towards the temple and the upper part of the cheek. On eyelid closing, laughing or smiling the lateral part of the muscle is responsible for creating the dynamic rhytids that appear at the lateral canthus as the so-called 'crows feet'.

In most cases, three or four injections are necessary in this area (Figure 4). The first is placed 1cm lateral to the lateral canthus, taking care to remain distant from the orbital rim to prevent product diffusion into extraocular muscles. The next is placed 1-1.5cm above this point, and a further one or two injections are placed below it, also 1-1.5cm apart, depending on the extent of the rhytids.

Figure 4. Botulinum toxin injection pattern and dose for treatment of lateral canthal rhytids. Doses refer to injections of Botox.

Dose

The Botox Facial Aesthetic Study Team carried out a double-blind, randomised, placebo controlled dose response study of Botox in the treatment of lateral canthal rhytids. Patients were randomised to receive 3, 6, 12 or 18U of Botox on one side and placebo on the other. All doses resulted in an improvement compared with placebo, but higher doses achieved greater wrinkle ablation and longer lasting results. There was no difference between the 12U and 18U groups so the authors concluded that the optimal dose for treating lateral canthal rhytids was 12U per side [4].

Ascher and colleagues [28] carried out a double-blind, placebo-controlled dose ranging study to identify the optimal dose of Dysport in the treatment of lateral canthal rhytids. Patients were randomised to receive 15, 30 or 45U of Dysport on one side and placebo on the other. Again all doses produced an improvement compared with placebo, but there was a significant dose response relationship with 30U and 45U delivering longer lasting results.

Lower Lid

Flynn and Carruthers demonstrated that a single injection of 2U Botox at the lower eyelid midpupillary line resulted in a reduction in lower eyelid dynamic rhytids and an increase in the palpebral aperture [29]. The same authors later performed a dose finding study, comparing 4U with 8U Botox in the lower eyelid. The incidence of complications increased at the higher dose, with all patients complaining of eyelid oedema and incomplete sphincter function. Consequently the authors recommended lower doses of 2U or 4U of Botox in the lower eyelid [30].

In the lower eyelid the orbicularis oculi muscle has a role in maintaining the position of the infraorbital fat pad in addition to its sphincter function. Paralysis of this muscle can result in herniation of the fat, resulting in a lower eyelid bag [31]. In clinical practice it is

impossible to identify preoperatively who will be affected by this complication and the author rarely uses this technique due to its inherent unpredictability.

The Botox Brow Lift

Eyebrow elevation by means of botulinum toxin injection has been well described in the literature and is very commonly practiced [32-38]. Careful and detailed aesthetic evaluation of the face is crucial before undertaking this procedure. All too often it is undertaken unnecessarily and results in an inadvertently aged and unnatural appearance.

In the lower face and neck, descent of the soft tissues is a characteristic feature of ageing. In the brow however, there is a paradoxical elevation in eyebrow position with age secondary to a hyperfunctioning frontalis muscle [39]. Brow lifting should only be undertaken in patients with genuine brow ptosis as a feature of ageing. This group of patients should be the minority.

The Botox brow lift takes advantage of the dynamic interplay of the muscles of facial expression in determining the position of the overlying skin. Broadly speaking, the muscles of facial expression can be divided into elevators and depressors. To create the Botox brow lift it is necessary to reduce the impact of the brow depressors, thereby potentiating the effect of the brow elevators.

The brow depressors are procerus, corrugator supercilii, depressor supercilii and the superolateral part of orbicularis oculi. The only brow elevator is frontalis, which must therefore be preserved when trying to create a chemical brow lift (Figure 5).

Figure 5. Injections points for chemical brow lift: injections to the high forehead, glabella and superolateral orbicularis. Doses refer to Botox.

Frankel [38] described the impact on eyebrow position of injecting 20U of Botox in the glabella in a standard five-point injection technique. He noted that, although this resulted in some medial brow elevation, maximal elevation was observed at the outer third of the brow. Ahn [36] subsequently documented the effect of injecting 7-10U of Botox into the lateral

orbicularis oculi fibres superior and lateral to the orbital rim. This resulted in a 1mm elevation in brow height medially and a 4.8mm elevation laterally. In practice, a combination of glabella and lateral orbicularis injections are normally used to achieve a brow lift [40].

Lower Face

The use of botulinum toxin products in the lower face and neck has been well described in recent years, although the results are not always as predictable and satisfying as in the upper face.

Neck

The early literature on botulinum toxin in the neck focused on injecting platysmal bands. Brandt and Bellman reported the first use of botulinum toxin in the neck in 1998. In his paper he described injecting platysmal bands with 50–100U of Botox, which he claimed resulted in a reduction in the appearance of horizontal rhytids as well as a tightening of the skin of the neck [41].

The following year Kane published a series of fifty patients in whom platysmal bands were treated with five to twenty units each, depending on the thickness of each band. All patients showed some degree of improvement in neck contour, although the author conceded that the improvement was limited by redundant skin (Kane 1999).

A multi-practice case series of 1500 treatments of the platysmal bands was published in the same year [42]. The treatment was carried out on the anterior platysmal bands bilaterally with three to five injections per band, generally with a dose of up to 100U per patient – although some received up to 250U of Botox. The authors subjectively reported satisfactory outcomes in 98.5% of patients. Adverse events included one percent of patients reporting neck weakness and one case of dysphagia that resolved with conservative management.

In 2007 Levy described a departure from injection of platysmal bands, which he called the Nefertiti neck lift after the ancient Egyptian Goddess depicted with a sharply defined neck and jawline. The theory underlying the technique is that platysma exerts a negative force on the lower face and neck, so paralysing it should create the opposite effect resulting in an upward lift to the neck and lower face. Levy described injecting five sites 1–1.5cm apart along the inferior border of the mandible and two injection sites in the superior pole of the posterior platysmal band. Each site was injected with two to three units of Botox, for a total dose of fifteen to twenty units per side. According to the author all patients had a noticeable improvement in the contour of their jawline and elevation of the skin. The technique had a favourable side effect profile, which the authors attributed to the lower doses used in comparison with other papers [43].

Oral Commissures

Traditionally, down turning of the corners of the mouth has been considered a surgical problem to be addressed by facelift surgery. In more recent years, facial fillers and fat augmentation have played an increasing role. Injection of botulinum toxin to the depressor anguli oris muscle can also help provide an elevation in this area [44]. A single injection of

two to five units of Botox or six to fifteen units of Dysport is placed in the most inferior and posterior part of the muscle to avoid diffusion into the nearby depressor labii inferioris [45].

In this area the results of botulinum toxin alone are modest and it is better to combine with other treatment modalities. When combined with filler injections, the overall result and duration of action is greater than when either technique is performed alone (Carruthers 2010, Custis 2010).

Chin

Over activity of the mentalis muscle can produce an unattractive peau d'orange dimpling on the chin. This can be managed effectively with 5U of Botox delivered through a single injection point at the level of the mental prominence [15].

Nose

Dynamic rhytids of the nose can be treated successfully with injection of three units of Botox into nasalis bilaterally [46]. Dynamic drooping of the nasal tip can also be corrected by injecting three units into depressor septi nasi at the base of the columella.

Lips

Injection of botulinum toxin can reduce the appearance of perioral lines ("smokers lines"). Treatment of these lines has the simultaneous benefit of providing an increase in lip eversion and the appearance of enhanced volume [47].

One study compared a total dose of 7.5U with 12U Botox, injected at four equally divided injection sites on the upper lip. Both doses produced a satisfactory appearance, although the higher dose resulted in a longer lasting result [48].

Gummy Smile

The gummy smile is characterised by excessive gingival show on smiling and is associated with an unattractive appearance. This can be corrected by injecting a small dose (usually two to three units) of Botox into the levator labii superioris alaeque nasi muscle on either side [49].

Masseter

The ideal female jaw is narrow and delicate in contrast with the male jaw, which is broad and defined. It is possible to reduce the jaw angle width by injecting botulinum toxin into the masseter muscle, which results in muscle atrophy and a reduction in the width of the jaw angle. Doses of 30-50U in two to three injection points per muscle have been reported to be successful [50, 51].

TREATING MALE PATIENTS

As a general rule, men can be treated using the same basic principles as women. Male patients tend to require higher doses and more injection sites, however, to account for their greater muscle mass and broader muscle sizes[52]. Little evidence-based guidance exists, but

from clinical experience doses of twenty to fifty percent higher than corresponding female doses are a useful starting point depending on muscle thickness.

COMBINATION THERAPY

Optimal management of the ageing face is achieved by combination therapy. This includes treating multiple areas of the face with botulinum toxin, combination of botulinum toxin with other non-surgical techniques and, where appropriate, combination of non-surgical with surgical techniques [53].

COMPLICATIONS

Complications following botulinum toxin treatment are generally uncommon, mild and self-limiting. They can occur either from a general reaction to the drug or by the spread of the toxin beyond the intended treatment site. Generalised reactions that have been reported include nausea, fatigue, malaise, flu-like symptoms and rashes at sites distant to the injection [54]. The effect of spread beyond the treatment zone will depend on which area is being treated and which muscle has been unintentionally affected.

Upper Lid Ptosis

When treating the glabella, diffusion of the toxin through the orbital septum into the levator palpebrae superioris results in an upper lid ptosis, which can last anywhere from two weeks to three months. It is difficult to quantify the precise risk of blepharoptosis. In earlier studies using Botox the rate of upper lid ptosis was reported to be as high as 5.4% [22]. However, as experience and injection techniques have developed more recent studies have not reported any incidence of eyelid ptosis using both Botox and Dysport [25]. In practice the actual rate of eyelid ptosis is probably greater than zero, although an estimate of less than one percent would seem reasonable when counselling patients. When ptosis does occur, its course can be improved with 0.5% apraclonidine eye drops three times per day which causes contraction of Müller's muscle and allows temporary reprieve until the effects of the drug wear off.

Brow Ptosis

Brow ptosis is a consequence of treatment of the frontalis muscle. If actively sought, it will be found to occur in the majority of patients undergoing treatment of the forehead [26]. It is incumbent upon the practitioner to anticipate the degree of brow ptosis that treatment of the forehead rhytids will create, discuss this with the patient and make a clinical decision of risk versus benefit to treating this area.

Strabismus

Strabismus is a potential complication of injections at the lateral or medial canthus where there is diffusion of toxin within the bony orbit. It is a rare complication and as such is difficult to quantify from the available literature. Where it has been reported it has generally settled with conservative management over a period of several weeks, but all cases should be referred for an ophthalmology opinion.

Upper Lip Ptosis

Injection sites placed too inferior from the lateral canthus can cause diffusion into the zygomaticus major muscle, which causes upper lip ptosis and an asymmetric smile. In one large study the incidence of this was approximately 0.2% [55].

Lower Lip Incompetence

Lower lip incompetence can result from inadvertent treatment of the depressor labii inferioris when targeting the depressor anguli oris muscle.

Neck Weakness, Hoarseness and Dysphagia

In the largest case series of treatments of the neck, 10% of patients reported transient neck pain. One per cent of patients reported neck weakness and 0.07% reported transient dysphagia [42].

Muscle Atrophy

Long-term repeated use of botulinum toxin will lead to disuse atrophy. The precise implications of this condition and the timescale over which it develops are yet to be fully described.

LONG-TERM FOLLOW UP

Despite the widespread practice of injecting botulinum toxin for over two decades now, there remains a lack of long-term prospective data in the scientific literature to document long-term outcomes and best practice treatment guidelines to optimise long-term outcomes.

Bulstrode and Grobbelaar [26] described their experience of patients receiving regular treatment with botulinum toxin over sixteen months, shown it was safe and effective over this time scale.

Rubin described a series of 311 patients who had well tolerated repeated treatments of 50U Dysport into the glabella [56]. A similar study by the Reloxin Investigational Group examining 50U of Dysport in up to six treatment cycles with an average follow up of seventeen months found a low incidence of adverse events, concluding that repeat treatments were safe and well tolerated [57].

Dailey treated a group of toxin naïve women with 20U of Botox in the glabella at four-month intervals over a period of two years. At the end of the study the researchers found that the effects of treatment remained evident at six months follow up, implying that results eventually last longer with longer-term treatment [58].

Binder (2006) described a case of identical twins, one of whom had been treated regularly with Botox for the last thirteen years and her sister who had not. In the sister who had not received treatment, visible lines were present on her face, even at rest. The sister who had regular treatment however did not display any resting rhytids.

TOPICAL APPLICATION OF BOTULINUM TOXIN – THE FUTURE?

There is currently much interest in producing a topically applied botulinum toxin formulation for the treatment of patients who are averse to needles and injections. A major barrier to this development has been creating a formulation that can be absorbed through skin and penetrate to muscle in a precise fashion. One formulation has been developed that appears to overcome this problem, with early clinical trials showing promising results in the treatment of lateral canthal rhytids [59,60]. Should this or any similar product make it to market, it is likely to be a prescription only medication expertly applied in a medical aesthetic clinic, rather than a more widely available over the counter product.

CONCLUSION

There can be little doubt as to the impact botulinum toxin drugs have had on aesthetic practice. Treatment with botulinum toxin has been demonstrated to be safe, effective, associated with minimal complications and reliably delivers a high degree of patient and surgeon satisfaction. Much progress has been made over the preceding two decades with regards to optimising injection techniques and dosing, but there still remain some important unanswered questions that need to be addressed by further studies, particularly with regards to the long-term management of patients with botulinum toxin.

At the current time there is plenty of anecdotal evidence to suggest that, used judiciously, the long-term aesthetic results of botulinum toxin are favourable. However, this has yet to be adequately quantified and important variables such as the optimal age to begin treatment, how regularly treatment should be repeated and for how long treatments should be repeated remains to be determined.

It is well documented that in the long-term the anti-wrinkle effect of botulinum toxins last progressively longer with each cycle. At some point it is likely that, even on discontinuing treatment, patients skin will not return to its pretreatment condition and at least some of the effects can be considered permanent. At what point this occurs, and how the management

should proceed thereafter is still unclear. It may be that in the long-term treatment is no longer necessary or perhaps should be continued on a less frequent 'maintenance' basis.

There is currently a trend towards utilizing botulinum toxins in very young patients who have yet to develop signs of ageing as a 'preventative' to stop wrinkles developing. There is a lack of evidence to support this practice and a great deal of consideration is required before this could be encouraged. In the long-term, muscle atrophy resulting from excessive repeated treatments leads to loss of volume from loss of muscle bulk. This can be particularly evident around eye area where the bony outline of the orbital rim becomes obvious from excessive treatment of the orbicularis oculi, resulting in an unnatural and inadvertently aged appearance.

It is likely that for the foreseeable future the use of botulinum toxins will continue to expand and as we learn more about long-term outcomes. Our approach to using these drugs will continue to evolve with a generally more conservative approach and a trend towards greater combination therapies with other non-surgical techniques in order to optimise long-term results.

Chapter 39

FACIAL FILLERS

Darren J. McKeown*

Aesthetic Medicine Institute, Glasgow, UK

KEY POINTS

Ageing is characterised by soft-tissue loss of volume and ptosis. There is also loss of facial skeletal support with age.

Fillers are most usefully classified as temporary, semi-permanent or permanent.

Collagen fillers have been largely superseded by hyaluronic acid owing to enzymatic reversibility, longer duration of action and a more favourable side-effect profile of the latter.

There is a high reported incidence of nodule formation following the use of hydroxyapatite and poly-L-lactic acid-based fillers.

Polymethylmethacrylate is the only permanent filler licensed by the FDA. Anecdotal evidence suggests complications are not uncommon and can be difficult to manage.

Blindness is a rare serious complication of filler injection, occurring most frequently when the filler material is autologous fat and the anatomical location is the nose.

INTRODUCTION

The last decade has seen dramatic advancement in our understanding of facial ageing. Thanks to a series of revolutionary anatomical studies, our traditional two-dimensional view of the ageing face has been firmly replaced by a more sophisticated three-dimensional model, at the heart of which lies the concept of volume loss. As the face ages, global loss and redistribution of volume occurs in both hard and soft tissues.

With an evolving understanding of facial ageing has come an appreciation of the importance of restoring volume in facial rejuvenation. Dermal fillers have assisted the therapeutic approach of plastic surgeons by providing a minimally invasive technique for

* Corresponding Author's Email: drdarrenmckeown@gmail.com.

volume restoration without the risks associated with traditional surgical approaches of structural fat grafts and implants.

Since the early days of collagen fillers, great advances in dermal filler technology now allow surgeons to produce consistent, reproducible and long lasting results. The contemporary aesthetic practitioner can choose from a wide range of filler products that can be tailored to suit individual indications.

FACIAL AGEING AND VOLUME LOSS

It was traditionally assumed that subcutaneous facial fat consisted of a single, uniform layer. More recent cadaver studies have instead revealed that subcutaneous fat is partitioned into discrete anatomic compartments and a significant proportion of facial ageing is due to characteristic changes that occur within each compartment. Cheek fat, also referred to as the malar fat pad, has three distinct compartments: medial, middle and lateral-temporal cheek fat. The forehead similarly contains three distinct fat compartments: medial, middle and lateral-temporal cheek fat that also extends to the cheek. Nasolabial fat exists as a distinct fat compartment. Subcutaneous orbital fat also consists of three separate compartments: superior, inferior and lateral determined by septal borders, whilst jowl fat is the most inferior fat compartment.

It has also been determined by cadaveric injection dye studies that distinct vascularised membranes define each fat compartment anatomically. Each compartment has its own identifiable blood vessel that carries the perforator blood supply to the overlying skin [1].

A German group studied age related changes to facial fat compartments by carrying out CT scans of unfixed cadaver heads. They demonstrated a general inferior shift and inferior volume redistribution of facial fat compartments with age. In addition, they noted compartment-specific changes including volume loss of the deep medial fat compartment in the cheek and in the buccal extension of the buccal fat pad. The implications of this study, whilst significant, need to be tempered against the age of the cadaver heads since a group of 54-75 years was compared with a group of 75-104 years, older than the typical aesthetic patient [2].

Volumetric contour changes are not limited to facial fat. Significant bony changes to the facial skeleton also take place with advancing age. In the upper face there is an increase in circumference of both the inferior and superior orbital rims, with a corresponding increase in the orbital aperture. In the midface there is an increase in the pyriform aperture, with a decrease in the glabellar and maxillary angles. In the lower face there is a reduction in the height of the body and ramus of the mandible, reduction in length of the mandibular body and widening of the mandibular angle [3].

Such anatomic studies demonstrate that facial ageing is a complex three-dimensional process. It is characterised not only by soft tissue volume loss but also by three-dimensional re-distribution of the soft and hard tissues of the face. The modern aesthetic practitioner's approach to anti-ageing therapy has therefore shifted focus to the restoration of facial volume and re-creation of more youthful facial contours.

CLASSIFICATION OF DERMAL FILLERS

There are currently over 150 dermal filler materials on the worldwide market. It is beyond the scope of this text to cover each material in detail. Instead, we will focus on those fillers that have been approved by the Food and Drug Administration (FDA) in America. There are fifteen such approved products at the time of writing. That is not to say there are no other useful fillers available elsewhere in the world, nor is it to say that all FDA fillers should be recommended. FDA approval does however serve as a useful benchmark in determining a minimum standard of research. Furthermore, the FDA list includes the most commonly used and clinically relevant products worldwide.

Dermal fillers can be variously classified (for instance by duration of effect, depth of implantation, composition material and stimulatory effect on the skin) but the duration of effect provides the most clinically useful classification, into: temporary, semi-permanent or permanent.

Temporary fillers such as collagen and hyaluronic acid (HA) gels have the benefit of allowing great flexibility and reversibility. They can be reversed by injection of collagenase or hyaluronidase respectively, allowing the surgeon the option of a 'get out of jail' card in the event of a serious adverse event. Semi-permanent and permanent fillers offer the promise of long lasting or even permanent correction. However, this needs to be balanced against a lack of predictability and control over the final result and the risk of long-term complications, which can be difficult, and in some cases impossible, to correct.

Temporary Fillers

Collagen

The first collagen products to be introduced were of bovine origin, available commercially as Zyderm and Zyplast (Allergan, Irvine, Ca). The FDA licensed Zyderm in 1981, whilst Zyplast was approved in 1985. The main difference between the two was that Zyplast contained cross-linked collagen, designed for deeper implantation within the dermis for the correction of deeper wrinkles, whilst Zyderm was non-cross-linked and suited to more superficial implantation. A multicentre study spanning six years and more than 5000 patients revealed the product to be safe, associated with only minor self-limiting complications [4].

Due to its bovine origin, however, hypersensitivity reactions were common and a skin test was mandatory prior to treatment. Hypersensitivity reactions nonetheless occurred after a negative skin test and were a major limitation of the early collagen products. To address this, the manufacturer developed synthetic human collagen under the trade names of Cosmoderm and Cosmoplast. The FDA approved these with no clinical trials as they were considered a simple source change to the original Zyderm and Zyplast products (that were subsequently withdrawn from the market by the manufacturer). Consequently there have never been substantial clinical trials on Cosmoderm or Cosmoplast, both of which are no longer available since the advent of HA fillers.

Two other porcine-derived collagen products have been approved by the FDA and produced under the trade names of Evolence (Colbar Lifescience, Herzliya, Isreal) and Fibrel (Mentor Corp, Goleta, Ca). Neither product is commercially available any longer.

Collagen was once considered the gold standard filler material and was a revolutionary product in its day. It was the first 'off the shelf' product to allow instant volume replacement and wrinkle reduction in a reliable and safe manner. However, injectable collagen had a relatively short duration of effect, results typically lasting just three to four months [5]. Since the introduction of hyaluronic acid, with its longer duration of effect and favourable side effect profile, collagen has been largely superseded and interest in it as a filler is now primarily historic.

Properties of commonly used collagen fillers are summarised in Table 1.

Hyaluronic Acid

The introduction of HA fillers has revolutionised the dermal filler market. HA is a polysaccharide found naturally within the skin, whose main function is to provide structure and maintain hydration within the dermis. There are a number of currently available HA products that have been approved by the FDA. These can be categorised according to the source of HA (animal or non-animal), concentration of HA within the product, degree of cross-linking, and their particulate or homogenous nature.

Restylane

Restylane was the first HA filler to be approved by the FDA in 2003. It is a non-animal sourced particulate gel containing 20mg/ml HA stabilised using BDDE (1,4-butaediol diglycidyl ether). Restylane contains 100,000 particles per millilitre. Its sister product, Restylane Perlane, contains 10,000 larger particles per millilitre and is designed for deeper implantation within the dermis for the correction of deeper lines and wrinkles.

The first large scale clinical trial of 158 patients injected with Restylane published in 1998 showed that effects persisted at eight months in over eighty percent of patients [6]. Another group reported their series of 1446 patients who underwent treatment of various facial areas with Restylane and found that 61% of patients remained satisfied with the results after nine months. They noted that the duration of effect appeared to vary depending on the area treated, with treatment of the nasolabial fold and glabella generally lasting longer than the lips [7].

Table 1. Summary of collagen fillers

Brand name	Source	Concentration	Cross linked	Commercially available
Zyderm	Bovine	35mg/ml	No	No
Zyplast	Bovine	35mg/ml	Yes	No
Cosmoderm	Human	35mg/ml	No	No
Cosmoplast	Human	35mg/ml	Yes	No
Evolence	Porcine	35mg/ml	Yes	No
Fibrel	Porcine	35mg/ml	Yes	No

A multicentre, randomised controlled trial comparing Restylane with bovine collagen (Zyplast) for the correction of nasolabial folds randomised 138 patients to receive Restylane or collagen to contralateral nasolabial folds [8]. The authors found that Restylane required less volume of product to achieve an optimal cosmetic result. Results were assessed at six months according to the degree of improvement on the Winkle Severity Rating Scale, demonstrating a superior result in nasolabial folds treated with Restylane and fewer side effects such as lumpiness or nodules. This study was the basis of Restylane obtaining FDA approval in America.

Hylaform

Hylaform was the first FDA-approved animal-based HA filler. It contains 5.5mg/ml avian-sourced HA and in unpublished – and therefore not peer reviewed - clinical data submitted to the FDA, was found to be equivalent in efficacy to bovine collagen (www.fda.gov). However bacterial-sourced HA (Perlane) has been found to be more efficacious in the ablation of wrinkles (as measured by the Wrinkle Severity Score) and was significantly longer lasting [9].

Juvederm

Juvederm contains bacterial-sourced HA and was first approved in 2006. Unlike the Restylane family of products in which product consistency is varied by changing particle size, Juvederm's consistency is varied by altering the concentration of HA and its degree of cross-linking. In the US, it is available in two formulations: Juvederm Ultra and Juvederm Ultra Plus. Both contain 24 mg/ml HA but the Ultra Plus product is more highly cross-linked.

A randomised, double-blind multicentre trial of 292 patients comparing Juvederm with bovine collagen (Zyplast) in the correction of nasolabial folds found clinically significant wrinkle reduction persisted at nine months in the Juvederm group but not the collagen group. Moreover, 78% of patients treated with Juvederm had a clinically significant improvement that persisted beyond one year [10]. A further comparison of Juvederm and Zyplast randomised 87 patients to receive each on contralateral nasolabial folds. In the Juvederm group, 96% of patients maintained their result at 24 weeks and 81% retained their result at one year. Conversely only 41% of patients maintained their results at 24 weeks in the Zyplast group. When patients were re-treated at the end of the study, less than half of the original volume of filler was required to achieve an optimal result [11].

Superior efficacy of Juvederm over Zyplast was confirmed in a further multicentre, double-blind, randomised trial comparing the two in the correction of moderate or severe nasolabial folds. In the study of 439 patients, Juvederm lasted considerably longer than Zyplast, with 88% of subjects preferring Juvederm [12].

Newer formulations of Juvederm containing lidocaine aim to reduce the procedural discomfort. During the first injection, pain is felt as the needle pierces the skin. The pain of product insertion is then less and subsequent injections in the same area are pain free as the initial dose of anaesthetic takes effect. There appear to be no associated increase in adverse events with this formulation [13,14].

Restylane vs. Juvederm

A randomised controlled trial of Restylane Perlane with Juvederm Ultra Plus compared treatment with each product on contralateral randomised nasolabial folds. After six months 70% of Juvederm treated folds maintained correction compared with 45% of Restylane Perlane treated folds. At twelve months, 71.4% of patients preferred the effects of Juvederm. The results were highly statistically significant [15].

Other Hyaluronic Acid products

Belotero is a bacterial-sourced HA filler approved by the FDA in 2011. It consists of 22.5mg/ml HA and, according to the manufacturer, is better able to fill dermal defects because of its 'dynamic, double cross-linking technology'. One randomised controlled trial, funded by the manufacturer, appears to show equivalent longevity to Restylane and Juvederm [16]. Captique was produced by the same manufacturer as Hylaform (Allergan, Irvine, Ca) and was identical except for the source of HA, which was bacterial rather than avian. Neither Hylaform nor Captique are available commercially any longer.

Prevelle (Mentor Corp, Santa Barba, Ca) is bacterial-sourced HA, similar to Captique and Hylaform except with more cross-linking to increase its durability. It is commercially available at present. There is little peer-reviewed literature to support its use.

Eleveess is a non-animal sourced HA filler approved by the FDA in 2006. There is little clinical evidence to support this product and there are a number of case reports of serious adverse events including persistent swelling, pain and nodule formation [17].

Duration of Effect of Hyaluronic Acid

Although the effects of HA are generally described as lasting six to twelve months, in practice the effects can remain visible for much longer. Individual case reports indicate clinical improvement persisting up to five years [18-20]. Evidence from histological studies indicates that the mechanical stretching effect of HA fillers on the dermis activates dermal fibroblasts to synthesise collagen de novo, which may account for the prolonged results often observed [21]. Recognition of a potentially very prolonged effect of HA is important to avoid unnecessary repeat treatments resulting in overcorrection and an unnatural result. The decision to carry out a repeat treatment should therefore be based on the findings of clinical examination rather than simply the chronology of previous injections.

Re-Treatment Intervals for Hyaluronic Acid

One study examined the effect of different re-treatment intervals to the nasolabial folds, with two groups of patients randomised to retreatment after either 4.5 or nine months. At eighteen months follow up, both groups maintained a similar degree of clinical improvement on the wrinkle severity rating scale, indicating that prolonged results were achieved regardless of the interval to initial re-treatment [22].

Safety

Initial safety data for Restylane prior to 2000 indicated an adverse event rate of one in 650 patients treated (0.15%). The majority of these were temporary events including localised granulomatous reactions, bacterial infection and acneiform or cystic lesions. Subsequently a manufacturing refinement, reducing the trace amounts of protein within the filler, reduced

adverse events to one in 1800 patients, with hypersensitivity occurring in one in every 5,000 patients treated [23].

There have been at least ten case reports of a granulomatous reaction to injectable HA [24-33]. There has also been a case report of severe angioedema acute hypersensitivity following injection of HA (Restylane) into the lips [34].

Properties of commonly used HA fillers are summarised in Table 2.

Semi-Permanent Fillers

Calcium Hydroxyapatite

Calcium hydroxyapatite (CaHA), is available under the trade name of Radiesse (Bioform Medical, San Mateo, Ca, USA). The product consists of calcium hydroxyapatite microspheres of 25-45µm diameter suspended in an aqueous gel carrier composed of caboxymethylcellulose, glycerine and water [35]. In an evaluator blinded randomised controlled trial comparing Radiesse with bovine collagen in the treatment of nasolabial folds on contralateral sides of the same patient, Radiesse provided a longer lasting correction with less volume of product required, albeit at the expense of prolonged oedema [35]. In comparison with HA fillers, CaHA has greater viscosity and elasticity which some users feel offers enhanced filling properties [36]. Due to the calcium hydroxyapatite content, Radiesse has often been promoted for the correction of bony defects such as nasal bridge deficiency [37].

One randomised study compared patient satisfaction following treatment with CaHA with two brands of HA (Restylane and Juvederm). The investigators found a greater patient satisfaction with the outcome of treatment from CaHA [38], although it is worth noting the study was funded by Bioform Medical.

CaHA does not come without its fair share of problems, particularly nodule formation and inflammatory reactions. One study of 609 patients demonstrated a 12.4% incidence of nodule formation following treatment of the lips using CaHA [39]. A further multicentre study of 113 patients primarily being treated for nasolabial folds and perioral rejuvenation found two patients required intralesional steroid injections for nodule formation and a further two required a course of oral steroids for ongoing inflammatory reactions [40]. There have also been case reports of nodule formation at sites distant to the injection site [41] as well as intraoral foreign body granulomatous nodules associated with injection in the facial soft tissues [42].

Poly-L-Lactic Acid (PLLA)

Poly-L-Lactic Acid (Sculptra) produces long-term volume enhancement by initiating a foreign body reaction and inflammatory response. Patients are typically treated with a series of three to four injections at one-month intervals. Over a nine-month period the PLLA is reabsorbed and replaced by a matrix of new collagen and proteoglycans [43]. Although the initial product is fully reabsorbed within the first year, the clinical appearance of enhanced volume typically persists for up to three years [44-46].

Table 2. Summary of HA fillers

Brand name	Source	Concentration	Cross linked	Commercially available
Restylane	Bacterial	20mg/ml	Yes	Yes

PLLA was initially marketed under the trade name of New Fill (Sanofi-Aventis, US), but this was subsequently removed from the market due to a high incidence of granulomatous reactions. The same product was reintroduced as Sculptra with different dilution and injection guidelines (Lowe NJ 2006).

In an FDA approval study, 233 patients were randomised to receive PLLA (Sculptra) and human collagen (CosmoPlast) on contralateral nasolabial folds. The effects of PLLA were maintained up to thirteen months, in comparison to three months for human collagen.

Despite the longer lasting results, the initial problems of New Fill have (perhaps unexpectedly) not gone away. In one large series of 210 cases, almost twenty percent of patients developed nodules. The researchers felt that the majority of these were clinically insignificant because they were only obvious on palpation. In the author's experience, however, patients continue to feel such irregularities when applying cosmetics and as such they remain a constant source of patient dissatisfaction. As well as the high incidence of palpable nodules, five patients required intralesional steroids and two required surgical excision of nodules, accepting the associated permanent scarring in approximately one percent of cases [47].

A further series of 100 cases was reported with eighteen serious adverse events. These included twelve cases of granuloma formation that were clinically significant, five cases of infection and three of long-term allergy [48]. There have also been numerous reports of late onset infections and granulomas [49-52]. Periorbital and temporal injection of PLLA has resulted in orbital infarction and permanent loss of vision [53].

In the author's experience, the volume enhancement produced by Sculptra is not youthful soft, supple skin but firm, fibrous tissue more reminiscent of extensive subcutaneous scarring.

Permanent Fillers

Polymethylmethacrylate

Polymethylmethacrylate (PMMA) is the only permanent filler to have been licensed by the FDA. A similar preparation has been available commercially under the trade names of Arteplast, Artecol and most recently Artefil. This family of products all contain approximately twenty percent PMMA suspended in an eighty percent bovine collagen matrix, which is gradually reabsorbed in the first three months allowing the PMMA particles to elicit

a foreign body reaction and generate new collagen or scar tissue [43]. Each generation of these fillers have been the result of manufacturing refinements, in particular avoiding particles of less than twenty microns in diameter. It has been hypothesised that smaller particles can be phagocytosed by macrophages and result in prolonged inflammatory reactions to the product [54].

Lemperle, the inventor of Artecol/Artefil, published the results of a postal survey of 950 patients conducted one to two years after treatment with PMMA. He reported a 91% patient satisfaction rate and a three percent complication rate [55].

In an FDA approval study, patients were randomised to receive either PMMA or collagen. At twelve months follow up, 86.7% of the PMMA group demonstrated continued augmentation with a similar rate of adverse events as the collagen control group [56]. In a further five year follow up study, funded by the product manufacturers, the same group were able to reassess half of the initial cohort treated with PMMA. They claimed there were no serious, unexpected long-term complications [54].

Other authors have disputed these findings, claiming a much higher personal complication rate with adverse events including serious granulomatous reactions occurring three or four years following treatment [48]. In one case series alone, PMMA was associated with 32 serious complications including infection, necrosis, granuloma, inflammatory reactions, hardening, stiffening and tissue immobility. The authors reported that these complications were, in general, very difficult and, in some cases, impossible to manage [57].

INJECTION AREAS

Perioral Rhytids

Lines and wrinkles in the perioral area - including the nasolabial folds, marionette lines and radial rhytids on the lips ("smokers lines") - are the commonest anatomical target for injectable fillers. Lines and wrinkles in this area form a single aesthetic unit and are usually treated in combination at the same treatment session. Product guidelines suggest that filler should be placed within the dermis in the area around the mouth. The dermis in this region is relatively thin, however, making true intradermal injection difficult. One histological study of nasolabial fold Juvederm injection found that the filler was actually located in the subcutaneous tissue, despite attempted intradermal injection and a satisfactory cosmetic outcome [58].

In one study of twenty patients using both Restylane and Perlane, investigators used an average of 5.6ml of HA to achieve optimal correction of the perioral area including nasolabial folds, marionette lines, oral commissures and radial lip lines [59]. In the author's practice a more conservative approach is taken in this region, with volumes of two to four millilitres of filler more typical. When injecting this area it is essential to envisage the region as a three dimensional, dynamic structure and to appreciate that overcorrection can inhibit the dynamics of the region and result in an unnatural appearance.

Lips

The lips are often described as the most ‘sensual’ feature on the face. Full lips are associated with youth and beauty, and lip augmentation is frequently requested by patients presenting to cosmetic clinics. A multicentre randomised, single blinded controlled trial comparing lip augmentation using injectable HA with no treatment found that HA injection produced significant improvements on a validated lip augmentation scale [60]. The results of lip augmentation with HA typically lasted six months or more.

HA injection into the lip is an exquisitely painful procedure and adequate anaesthesia is a prerequisite for a slow, controlled and precise injection. Anaesthesia is best achieved using infraorbital and mental nerve blocks, approached through the upper and lower buccal sulci respectively. There is little evidence to support the optimal anatomical layer of filler injection. Some prefer to inject the filler material deep within the muscle layer of the lip. It is the author’s opinion that this can create an unnatural and lumpy result when the lip moves and it is therefore better to place the filler material more superficially in the potential space between mucosa and the muscle.

Injections can be carried out in an antegrade or retrograde manner, although again little evidence supports either technique. It is the author’s preference to use an antegrade flow technique, which allows the filler to dissect its own way forward in the natural tissue space. Once the tip of the needle is located in the correct plane the injected filler creates its own natural dissection plane and avoids multi-level product placement. The needle can be inserted in a lateral to medial direction or vertically in a superior to inferior direction, which is the author’s preference. This technique encourages the product to flow not only laterally along the border of the lip, but inferiorly in to the red part of the lip, which produces a more harmonious and natural augmentation.

Tear Trough

The tear trough, or nasojugal groove, extends inferolaterally from the medial canthus towards the mid-pupillary line and denotes the junction between the lower eyelid and the upper cheek [61]. A true osseocutaneous ligament, termed the tear trough ligament, has recently been identified in this region [62]. With advancing age the tear trough becomes deeper as volume is lost from the midface and orbital rim.

Injection of HA filler to augment and rejuvenate the tear trough was first described in 2005 [63]. The author described superficial injections of Restylane with a high patient satisfaction rating of 92%, although few others have been able to replicate these results. Lambros described a deeper plane of injection on either the suborbicularis or suprapariosteal plane with firm massage to ensure a smooth result, using 0.2-0.4ml of filler per side. He noted that very often the filler seemed to last much longer in this region [64].

One group attempted to quantify filler longevity in the tear trough using volumetric 3D image analysis. The average filler volume was 0.21ml per side with no patients receiving more than 0.5ml per side. At 14.4 months average follow up, 85% of the initial filler volume persisted [65]. Indeed, there have been clinical reports of HA persisting for five years in the tear trough. Some have attributed the longer lasting result in this region to the relative lack of tissue mobility [20].

It would therefore appear that a small injection volume in a deep plane produces effective and long-lasting correction of the tear trough deformity. The tear trough is a difficult area to treat, with minor irregularities in the surface of the filler being apparent through the thin overlying skin creating a visual deformity. Experienced injectors only should therefore attempt tear trough injections.

Cheeks

Volume restoration to the cheeks and midface can be one of the most gratifying minimally invasive aesthetic procedures, associated with a high degree of patient satisfaction and reported to enhance the patient's own feelings of attractiveness [66].

As a general rule, high viscosity HA fillers are ideal for cheek augmentation [67]. The cheek can be filled using a linear threading or serial puncture injection technique [68] although the author's preferred technique is to use a blunt-tipped cannula from a single point inferior and lateral to the outer canthus. A sharp-tipped needle is used to create a small stab incision for entry of the cannula. This allows access to the entire cheek and midfacial area with a single needle point, minimizing the risk of bruising and swelling post-treatment. A small (0.1ml) injection of two percent lidocaine with 1:200,000 adrenaline at the planned site of cannula entry is sufficient to ensure a pain-free procedure and reduce the risk of entry site bleeding or bruising.

Overcorrection of the cheek should be avoided at all costs. In some younger patients as little as 0.4ml per side will provide enough augmentation whilst maintaining a natural look (Figure 1). Overcorrection in the cheek may appear acceptable in a resting patient but becomes immediately obvious and unnatural when the patient animates in laughing or smiling. It is therefore always best to undercorrect the cheek, review the patient two weeks later and make a decision on whether to add further volume at that stage.

Figure 1. Before (left) and after (right) 0.4cc hyaluronic acid in each cheek plus 0.3cc to the right and 0.5cc hyaluronic acid to the left nasolabial fold. The patient also underwent botulinum toxin injections to the glabella and forehead.

Treatment of the cheek area is almost always combined with treatment of other areas in the adjacent aesthetic units, in particular the nasolabial fold and tear trough. In some cases, injection of filler into the deep medial fat compartment of the cheek alone will provide enough correction of the tear trough deformity without formal treatment of the tear trough itself (Figure 2).

Volume restoration in the cheek usually lasts for a prolonged period of time in clinical practice, with most patients opting to have it performed once per year. A three-dimensional volume analysis found that 65.8% of the initial filler volume was still present in the cheek after six months [69]. If a patient therefore returns to the clinic requesting further augmentation before the full effects have worn off, it is important to reduce the injection volume from the first treatment record to avoid over-correction.

Temples

Hollowing of the temporal fossa, due to loss of volume from the lateral temporal subcutaneous fat pad or atrophy of the temporal extension of the buccal fat pad, contribute to the appearance of ageing in the upper face. Volume restoration in this area with HA can provide an effective rejuvenation of the upper face.

In a study of twenty patients undergoing temple injections of Restylane Perlane to the temples, Ross & Malhotra recorded an 81% patient satisfaction rate. Most patients received one millilitre of filler per side, except one patient who received three millilitres due to severe asymmetry [70]. In an effort to enhance patient satisfaction and avoid contour irregularities sometimes seen when injecting the thin skin of the temple, Lambros described a technique of diluting filler on a 2:1 diluent (normal saline or lidocaine) to filler ratio. The author claimed this technique, “the dilution solution”, resulted in a smoother look and improved patient satisfaction [71].

Figure 2. Before (left) and after (right) 2ml hyaluronic acid injected in the deep medial fat compartment bilaterally, demonstrating effacement of the tear trough deformity without any injections in the tear trough itself. The patient also had 2.4ml hyaluronic acid injected in the perioral rhytids and botulinum toxin injections in the glabella and forehead.

COMPLICATIONS

The advent of minimally invasive aesthetic medicine has reduced the risk of major complications compared with invasive surgical techniques, but adverse events have not been eliminated and vary according to the product used, its indication and the skill and experience of the injector. Practitioners should fully understand and appraise their patients of the risk of adverse events. Most are minor and self-limiting but serious life-changing complications can occur and it is vital that this is communicated to the prospective patient.

Localised Adverse Reactions

The majority of adverse events are localised reactions such as erythema, bruising, pain and swelling. These are to be expected but their incidence can be reduced by careful injection technique. Injections that increase dissection of the subdermal plane (fan like needle use, rapid injection, rapid flow rate and higher injection volumes) increase the risk of localised adverse events, although multiple small volume injections and depth of injection do not appear to have any impact [72].

Granuloma

Foreign body granulomas have been reported after use of every type of dermal filler [24,73,74]. The precise incidence of granuloma formation is difficult to quantify since it is typically a late event occurring months or years after the initial treatment and as such is often under-reported. The incidence varies depending on the nature of the filler, its surface structure and properties, content of impurities but not its primary biocompatibility or the volume injected [75]. Due to the relatively low incidence of granuloma formation there is a lack of good quality clinical trials on how best to manage them, so management is based on expert opinion rather than evidence. As a general rule most untreated granulomas will grow to approximately the size of a bean and eventually resolve in one to five years, although experts advocate the use of intralesional and oral steroid treatment to expedite the resolution [75].

Necrosis

Necrosis is a potential complication where any foreign material has been injected into the skin or subcutaneous tissue [76]. It can result from arterial embolisation of filler material or as a result of swelling around the filler material causing occlusion of the arterial supply distally. Again the precise risk is difficult to quantify due to the event being relatively rare. Nonetheless one large case series of bovine collagen injections found a necrosis incidence of approximately 0.1% [77]. It is likely that other fillers with a similar mode of action have a similar risk profile.

Where a permanent or semi-permanent filler material has been used there can be little meaningful intervention to prevent the development of necrosis after the initial signs of arterial occlusion have developed. If a HA has been used, however, prompt recognition of the signs of arterial occlusion – pale skin and disproportionate pain – and immediate injection of hyaluronidase to dissolve the filler may prevent progression to necrosis and avoid the scarring and reconstructive defect [78,79].

Blindness

One of the most serious complications of dermal filler injections is permanent visual loss resulting from inadvertent injection into a branch of the ophthalmic artery, retrograde embolisation and occlusion of the retinal artery. This is a rare but devastating complication of any filler injection in the upper face and scalp.

There have been at least 34 case reports published in the medical literature documenting blindness following filler injections. Fifteen cases have been reported after fat injections, nineteen following injection of other materials including steroids (four cases), collagen (three cases), silicone (three cases), PLLA (two cases), HA (two cases), CaHA (one case), paraffin (one case), PMMA (two cases) and one case of an unknown substance (Table 3).

Table 3. Cases of blindness by filler material

Filler material	Cases of blindness
Fat	15
Steroids	4
Collagen	3
Silicone	3
PLLA	2
Hyaluronic acid	2
PMMA	2
Calcium hydroxyapatite	1
Paraffin	1
Unknown	1

Table 4. Injection sites for synthetic materials to result in blindness

Injection site	Reports of blindness
Nose	7
Glabella	4
Scalp	3
Forehead	2
Temple	2
Peri-orbital	1

The injection sites that have resulted in blindness have included the nose (seven cases), glabella (four cases), scalp (three cases), forehead (two cases), temple (two cases) and one case of peri-orbital injection (Table 4). Given that the most commonly reported injection site

causing blindness is itself one of the least commonly injected areas - the nose - this may be a particularly high-risk region, and this should be discussed with patients at the pretreatment consultation [80].

CONCLUSION

Modern dermal filler technology provides a means of addressing many signs of facial ageing through a relatively quick and easy injection. Using dermal fillers it is possible to address many signs of ageing that have been traditionally considered a 'surgical' problem, whilst minimizing the risk of side effects and complications.

As dermal filler treatment has evolved to become a normal part of life for many men and women, the market has expanded and the number of potential filler materials available internationally has increased exponentially. In an under-regulated field of medical practice it is essential that physicians take the lead in demanding high quality products from drug companies and only offer patients products that are supported by solid clinical evidence.

As the field of minimally invasive aesthetic medicine becomes a mainstream part of life, it is easy for physicians and patients to forget that such procedures constitute real, medical procedures with a risk of side effects and complications. To minimise the risks of such complications and to ensure prompt recognition and initiation of side effect management it is essential that only appropriately trained and experienced physicians should carry out this work. As well as being able to reduce the risk of side effects through proper training and experience, physicians should also be able to recognise the early signs of complications and initiate prompt treatment to minimise the risk of long-term consequences.

As the demand for minimally invasive procedures continues to rise, and our understanding of facial ageing continues to evolve, it is becoming increasingly clear that the best results in anti-ageing therapy are achieved through a combined approach. The consulting physician should not be focused on one single treatment modality but consider a combination of treatment approaches in order to optimise results. Topical products, botulinum toxins, platelet rich plasma, chemical peels, laser, IPL and surgical intervention should all be considered. By combining strategies, we can continue to offer our patients the most effective solutions to their aesthetic concerns.

Chapter 40

BODY CONTOURING USING IMPLANT PROSTHESES

Daniel Saleh* and Mohammed Riaz†

Castle Hill Hospital, Cottingham, UK

KEY POINTS

- The largest experience of implant placement for augmentation gluteoplasty is intramuscular.
- Complications of augmentation gluteoplasty appear to be high but the incidence and outcomes of salvage surgery are unclear.
- The preferred plane of calf augmentation is subaponeurotic.
- Male pectoral augmentation is an uncommon procedure but subjective patient satisfaction is high.
- Upper limb contour augmentation, although uncommon, is most commonly performed for posttraumatic deformity with acceptable outcomes.
- No validated aesthetic outcomes have been reported for gluteal, calf, pectoral or upper limb implant augmentation. No comparisons to alternate methods of augmentation are available in the current literature.

INTRODUCTION

Alloplastic implants have been used in a number of guises to enhance the aesthetic appearance of body parts. The largest worldwide experience is of the use of breast implants for aesthetic augmentation. Numerous other implants now exist and are used to enhance the limbs and trunk. Practices vary between cultures and gender, as evident in the current literature. This chapter focuses on the use of implants in the limbs and trunk and excludes the breast, which is dealt with separately in Chapter 6.

GLUTEAL AUGMENTATION

The gluteal region of men and women is considered an important aesthetic element in all cultures, although there is cultural diversity as to what constitutes an attractive buttock. Most published work originates from South America. Cuenca-Guerra and colleagues were the first to scrutinise over 1200 photographs of young female adult buttocks [1], assessing standard posterior, three-quarter profile and full lateral views. Six plastic surgeons separately analysed these images for specific features of beauty [1]. A validated scale does not exist but four features were consistent among the assessors that were felt to contribute to beautiful buttocks (Table 1). [1] They subsequently proposed a classification of buttock morphology primarily based on antero-posterior projection and gluteal and peri-gluteal fat volume [1] that was correlated to methods of augmentation (Table 2).

Table 1. Ideal gluteal aesthetic components identified by Cuenca-Guerra et al. [1]

Anatomical feature	Description
Lateral gluteal depression	Hollowing at the lateral buttock between insertion of Gluteus medius superiorly and vastus lateralis inferiorly
Infragluteal fold	Horizontal fold at the inferomedial buttock. Formed by insertion of Semitendinosus and biceps femoris into the ischial tuberosity.
Supra-gluteal fossettes	Formed by the posterior superior iliac spines (PSIS)
“V-shaped” crease	A fold at the cranial end of the medial buttock where the two sides of the “v” point toward the fossettes.

Table 2. Type classification of buttock according to morphology as described by Cuenca-Guerra et al.

Type	Morphology	Surgical correction
1	Excess gluteal and lumbar fat	Liposuction
2	Excess supra- and subgluteal fat only (flat buttock)	Small based round high profile implants for projection
3	Lumbo-sacral hyperlordosis (exaggerated A-P projection)	Almond shaped wide based low profile implants
4	Limited gluteal fat, poor gluteal projection	Wide based high profile implants
5	Ptotic buttocks of older persons	Skin excision +/- implant id required.

Bartles was the first to augment the buttock (using a breast prosthesis) [2] and the number of buttock augmentations performed within the Americas increased sixfold between 2002 and 2008. [3] Four planes have been described for implant placement: subcutaneous, intramuscular and submuscular and sub-fascial (the gluteal fascia).

EVOLUTION OF TECHNIQUES

Gonzalez-Ulloa described the subcutaneous pocket for implant augmentation [4] and his subsequent report [5] showed the procedure was reproducible. The method did not become

popular, since division of the aponeurotic and fascial attachments between the skin, subcutaneous fascia and underlying gluteal muscle left the implant mobile within its dissected pocket. Therefore potential implant visibility, palpability, ptosis and/or displacement and seroma were common. Evidence for this is anecdotal as no long-term data has been reported after Gonzalez-Ulloa's description and ten-year report, which did not discuss postoperative results. However, it appears that surgeons had poor early results and abandoned the subcutaneous plane.

Robles and co-workers provided the first description of subgluteus maximus (submuscular) implant placement. [6] Proponents cited decreased implant displacement, seroma and ptosis, and felt that submuscular placement would provide better aesthetic results versus subcutaneous placement. Hidalgo has reported the most comprehensive analysis of submuscular implant placement, and overall five percent of 97 patients augmented required reoperation for complications. A further thirteen percent of this cohort experienced minor complications that did not mandate reoperation, including one seroma. [7] Nonetheless detractors of submuscular placement cited particular disadvantages related to the limits of the submuscular pocket: it cannot be dissected beyond the inferior margin of the piriformis muscle since operative injury or latent implant pressure could disturb the sciatic nerve. A potential consequence of this is a "high riding" prosthesis leaving the inferior pole of the buttock relatively empty, resulting in unsatisfactory aesthetic outcomes. [8] No further series of submuscular implant placement have been reported and none offer formal aesthetic evaluation.

Following Roble's submuscular description, Vergara and colleague described the intramuscular pocket for buttock augmentation. [9] Following anatomical evaluation they advocated the use of an intragluteus maximus plane to avoid sciatic nerve injury (allowing dissection beyond the inferior limit of the piriformis), provide complete implant coverage with muscle, prevent ptosis and migration due to muscle support, and protect the implant from wound dehiscence. [9] The anatomical study showed there to be a natural intramuscular plane that could be bluntly dissected to provide a larger and more easily identifiable pocket than the submuscular space. [9] A subsequent report of 160 cases exhibited a complication rate of ten percent [10] including implant asymmetry (2.5%), capsular contracture (2%) and rupture (0.5%), with no infections. Haematoma rates were not clearly documented. Reoperation was required in four percent of cases and no patients experienced sciatic nerve injury or dysfunction. [9] Mendieta summarised a case series of 73 patients in whom there were no sciatic nerve sequelae or capsular contractures, but wound dehiscence occurred in thirty percent [11], all in the second postoperative week, thought to be related to patient mobilisation. Relatively high dehiscence rates were thought to have been due to a combination of bilateral tension on the intergluteal wound, relative poor vascularity of the midline incision and use of large implants. However in the majority of cases implant removal was not needed because muscle coverage of the prosthesis remained intact. [11] Interestingly the same author subsequently adopted a paragluteal crease incision and reported only one dehiscence in a cohort of eighteen patients using that approach. [12] Again, no sciatic nerve injuries were observed and implant migration was diagnosed in two percent of cases. [12]

Gonzalez provided a detailed report of a novel method for optimizing the surgical dissection of the intramuscular pocket. [8] In the largest series to date, 746 patients had gluteoplasty, 650 patients were primary aesthetic augmentation cases and the remainder were reconstructive cases such as poliomyelitis deformity correction. Although the results were not

subdivided to permit focus on the aesthetic cases, complications were uncommon overall [8]: no capsular contractures or nerve injuries were observed; infection occurred in four cases; one seroma required drainage; and there were two cases of implant migration requiring re-operation. However, the wound dehiscence rate was 14%. [8] Serra and colleagues detailed 105 intramuscular gluteoplasties in which there were nine percent seroma, five percent dehiscence and one percent infection rates. [13] However the seroma rate decreased to two percent overall once the surgical dead space was routinely closed with placating sutures and implant migration was eliminated. [13] Serra and co-workers have subsequently modified their technique for intramuscular augmentation to try reduce the complication rate. [14] The supra-gluteal fascia pocket created to allow intramuscular dissection was reduced in size, without undermining the skin flap in the midline. [14] This modified technique reduced the overall complication rate from 35% to 5%. However, the majority of patients that had the modified technique also had liposuction and it is unclear what effect, if any, this may have had on overall outcomes. [14]

The most recent series of intramuscular (including 154 subfascial and 46 intramuscular) gluteoplasties reported a 5.5% infection rate and 3% implant migration, [13] the author going on to adopt the subfascial method described by de la Pena. [3, 15] Like other authors, this change was driven by the significant degree of postoperative pain after muscular dissection, a slow return to ambulation and subjective difficulty in maintaining lower gluteal fullness. [3,8,10,12] Interestingly none of the reports for intramuscular augmentation include consistent reporting of all types of pertinent postoperative sequelae. In addition no authors have used objective surgeon or patient assessment of aesthetic outcomes for defined periods postoperatively. However, Serra et al. did perform postoperative computed tomographic (CT) scans to assess muscle atrophy and implant position for intramuscular augmentation. [16] The implants did not have physical sequelae for the patients, but muscle atrophy was consistent. All oval implants had re-orientated from vertical placement into an oblique position in line with the muscle fibres [16] but this had no effect on the aesthetic outcome.

The subfascial gluteoplasty is the latest surgical modification for implant insertion. Despite its relatively recent description in 2004, this method had been deployed by De La Pena for “years”. [17] A subfascial implant is attractive because theoretically it may reduce postoperative pain as no muscular dissection is carried out. The thick gluteal fascia (aponeurosis) can maintain implant position as demonstrated in a cadaveric study. [18] De la Pena and co-workers advocate this particular method of gluteoplasty for thin, young patients of a generally athletic build. [15] This group state a less than one percent deep infection rate in their experience and no seromas or haematomas [15], however a definitive case series is not provided in the report and rates of capsular contracture, implant migration and aesthetic evaluation objectively are not published. Although subfascial gluteoplasty carried a similar overall complication rate (of thirteen percent) versus intramuscular procedures performed by the same surgeon, the author believes subfascial placement carries better aesthetic outcomes and an easier postoperative course for the patient. [3] The exact complication rate is difficult to ascertain but has been reported as in the region of 32%; predominantly dehiscence and seroma formation were reported. [19] A smaller series with a similar operative technique and incision demonstrated a 51% complication rate for 31 patients using the same prostheses as De La Pena. [15,19] The majority of these were wound dehiscence and seroma formation. [19] Major complications were observed in 35% of cases, 15% of these were secondary to implant migration, rotation, flipping and patient dissatisfaction. Furthermore 19% of the

major complications were related to seroma formation. [19] However this study did report a 100% rate of palpable implant at the lower pole of the buttock, which has not been the case for intra and submuscular placement of prostheses.

A recent survey of American society of plastic surgeons that assessed data submitted for 2226 gluteal augmentations, showed the preferred plane of implant placement was intramuscular (68%). [20] Although complication rates for different planes were not directly compared, the overall complication rate was 38%, the most common being wound dehiscence (7.9%). [20] Although reporting of complications is not consistent for augmentation gluteoplasty, intramuscular implant placement appears to carry less overall complications.

Figure 1. Summary of the complication rates presented in the literature for gluteal augmentation in submuscular, intramuscular or subfascial planes to date.

Breast implants were first used to augment the gluteal region. The heterogeneous nature of reporting means exact complication rates cannot be accurately correlated to implant type used. The current implants available can be broadly grouped as custom made solid silicone, silicone gel and silicone cohesive gel. Some authors prefer either gel or cohesive gel because they afford softer feel. [6,15] Implants are also available in round or anatomic (oval) shape. Round implants probably provide better posterior projection although this is not a validated observation. There are a number of manufacturers providing various sized implants, and the cohesive gel implants can be textured which may contribute to prevention of implant migration. It is possible different implant types have distinct complication profiles. This has not been assessed in any trials and was not objectively scrutinised in the survey performed by Mofid and colleagues. [20]

There is a paucity of objective aesthetic assessment across all methods described and studied for gluteoplasty. The largest cumulative experience is with intramuscular implantation and despite there being only case series evidence, they appear to carry less complications versus subcutaneous, submuscular and subfascial prosthetic placement. Unfortunately stratification of minor and major complications is inconsistent in this body of literature and it is unclear whether certain infections were deep or superficial. Despite the volume of gluteal

augmentations performed, patient satisfaction and aesthetic outcome studies are yet to be forthcoming and should be a priority in future study for this procedure. Figure 1 summarises the cumulative published experience.

IMPLANT PREPARATION

Preparation of the implant and pocket before implant insertion is important given the proximity of the anus and sexual organs. Although there is no evidence of a higher commensal bacterial count in the gluteal region compared to other body regions, it is logical to ensure great care during implant handling and insertion.

De la Pena advocates plugging the anus with a povidone soaked swab at the time of skin preparation. Once the pocket is fashioned the selected implant is soaked in an antibiotic solution and inserted with a “no touch” technique familiar to insertion of breast implants. [17] Rather than soak the implant, Mendieta prefers to wash the pocket out with antibiotic solution (the antimicrobial agent is not specified). [11] No infections were reported in this series despite 30% dehiscence rate treated with antibiotics. Vergara also isolates the anus by suturing a swab in place but no local antibiotic therapy was used. However an intraoperative and one week course of intravenous and oral antibiotics were routinely used and no infections were reported. [9]

The most comprehensive preparation was described by Senderoff. [3] The anus was covered with a povidone soaked swab and the implant was soaked in povidone and saline. The intergluteal region was then re-prepped in a standard fashion ready for implant insertion. Later in this authors experience patients were routinely provided antiseptic wash to use the night before and morning of surgery.

The remaining series discussed do not specify an antimicrobial regimen or particular method of implant and/or pocket preparation. We believe it is unlikely these investigators do not have a routine practice and it is probable some form of particular implant preparation exists. There is no one study that has compared methods of improving sterility to infection rates. Moreover it is hard to directly compare these series given the heterogeneous methods used, which have probably evolved from their preferred methods of breast implant preparation. This is exemplified by Mofid and co-workers’ survey that showed not all surgeons use postoperative drains and the majority irrigate the implant pocket with antibiotics. [20]

The use of suction drainage placed in the plane of the implant is more consistent and used by nearly all authors. [3,5,6,8-11,13,17] Hidalgo explicitly does not use drains and only reported one seroma in his series of 97 patients. [7] Most authors place drains because unlike augmentation mammoplasty the dissection within or around the gluteus muscle can be extensive, perhaps inciting a potentially larger seroma formation. However there is no correlation in the literature presented between drain use, seroma rate and infection.

CALF AUGMENTATION

The posterior leg is not defined as a secondary sexual characteristic but calves do have an important place in cultural perceptions of beauty. With the advent of prosthetic enhancement it could be argued a natural progression to calf augmentation was inevitable. Unlike other body contouring procedures with implants, men, particularly body builders, primarily seek calf implants. The first implant to be used for the purpose of augmenting the posterior leg was carried out by Carlsen. [21]

Numerous studies have assessed the outcomes of this procedure with different surgical approaches. It is evident from the available body of literature that confusing terms of implant placement have been used. On scrutiny of the surgical techniques provided, the plane of dissection and implant placement have been re-named in this text for the sake of clarity. The implant pockets are described as subcrural which refers to the plane deep to the crural or popliteal fascia overlying the fascia/aponeurosis of the gastrocnemius muscle. Subfascial describes a plane deep to the gastrocnemius fascia overlying the muscle proper and in this text will be referred to as subaponeurotic to avoid confusion. 'Submuscular' is in the areolar plane between gastrocnemius and soleus muscles and 'supraperiosteal' lies anterior to the posterior tibial periosteum, completely submuscular. However, surgical exposure is more constant and all authors have preference for an incision through the medial popliteal crease.

The particular aesthetic ideals were first delineated through photographic and anatomical analysis by Ceunca-Guerra and co-worker. [22] Eight surgeons independently rated the ideal aesthetics of the calf region. The standard photograph set included a posterior, lateral and three quarter posterior view of the calf. The group of surgeon assessors highlighted five distinct types of posterior leg that were aesthetically deficient with particular attention to anteroposterior and laterolateral projections. [22] It is unclear whether the ratings were adjusted for intraobserver errors and validated. The published evidence that has followed this description has not however grouped patients using this method. This may be because of the heterogeneity of this anatomical site or that surgeons do not feel the exact morphology of the posterior leg dictates the approach to augmentation. Muscle bulk, subcutaneous fat and skin quality can differ widely. Generally most surgeons aspire to create greater laterolateral width together with medial antero-posterior projection. [22]

Von Szalay reported the first series of subaponeurotic implants but did not accurately quantify the cohort size stating "more than 25 cases". [23] Of these cases one patient experienced deep sepsis and one requested implant removal giving at most a re-operation rate of 8% and 4% incidence of capsular contracture [23] A larger series of 121 subaponeurotic patients reported a re-operation rate of 7% due to one haematoma, two deep infections, four capsular contractures and one implant migration. Aesthetic outcomes were reported as high, but not qualified by the author. [24] Montellano also augmented patients using a subaponeurotic method in 68 cases, emphasizing a successful surgical technique but no stratification of patient outcomes or complications was provided. [25] Lemperle offered a more comprehensive assessment of 14 subaponeurotic implant patients reporting satisfactory outcomes with re-operation in 14%; one seroma and one visible implant. [26] None of these studies have reported objective or subjective patient satisfaction rates.

Felicio reported a cohort of 100 cases of augmentation, ninety of which were for pure aesthetic purposes and included cases of subcrural and subaponeurotic implant placement.

[27] Although the surgical groups were not discussed separately, an overall complication rate of seven percent was observed and three percent required re-operation. Two patients were unhappy with aesthetic outcomes and one implant migrated superiorly necessitating removal. A small, subsequent cohort of eleven patients experienced no re-operations and no complications for implants placed in the subaponeurotic plane. [28]

Kalixto and colleagues presented eight cases, including three revision cases from previous aesthetic augmentation using a novel surgical approach. [29] A submuscular plane was used citing a safer dissection in the avascular areolar plane, no potential injury to neurovascular structures and avoidance of implant visibility were cited as advantages. However, prior to this series there was no clear consensus in the literature that implant visibility has been reported by patients as undesirable in other planes of placement. The authors concluded that patients experienced greater postoperative pain due to the intermuscular dissection and no data was published for complications or aesthetic outcomes. [29] The submuscular approach was also advocated recently by Ceunca-Guerra et al. also stating this reduces implant show and seroma but results of their clinical experience were not included. [22] Nunes and colleagues are the only team to describe the supra-periosteal placement of prostheses. [30] This unique experience used a total supra-periosteal plane for augmentation with closed fasciotomy of the posterior compartment to increase muscle herniation hence reducing the size of prosthesis required and decreasing implant show. [30] No complications at all were reported and no aesthetic evaluation was presented. [30]

The most recent cohorts have been subaponeurotic augmentations. Niechajev presented fourteen cases with only one re-operation for patient dissatisfaction. [31] In the only study to examine patient perceptions of their aesthetic outcome, Pereira et al. assessed 53 subaponeurotic augmentations and showed more than seventy percent of patients felt their aesthetic appearance was very good, whereas two percent had poor appearance. [32] No infections, capsular contractions or implant displacements were observed, although six percent required operative drainage of seroma. Furthermore eight percent of the cohort developed hypertrophic scars. A series of 63 patients who all had subaponeurotic bilateral calf implants reported a similar complication profile. [33] Early postoperative pain was experienced by 11%, seroma in 21% and dehiscence in 7%. One patient required explantation for infection, two implants ruptured and four implants had significant capsular contracture. Revision surgery for these complications did not result in recurrent problems but follow-up thereafter is unclear. The authors did try to assess aesthetic outcomes using a non-validated scale questionnaire. The mean aesthetic index was 9.8, indicating high satisfaction.

Overall the current evidence lacks detailed aesthetic evaluation of postoperative appearance and follow-up durations are scantily reported. The majority of cases are subaponeurotic and appear to offer relatively low complications rates. In particular there is little reference to problems such as implant show, yet authors who prefer submuscular or suprapariosteal placement anecdotally refer to this as a significant issue associated with subcrural or aponeurotic augmentation. Furthermore there is only one report of implant displacement using the subaponeurotic plane. Currently the majority of experience is with a subaponeurotic approach and until large series or a randomised series is devised with patient aesthetic evaluation a superior method cannot be determined.

PECTORAL AUGMENTATION

Implants have also been used for body contouring of the male chest. The first series of implants for chest wall deformities (including female radiation necrosis) used custom made silicon prostheses placed subcutaneously. [34] Four males had correction of anterior thoracic wall abnormalities. Although there was no between groups analysis, 35% of the seventeen patients treated by this method experienced complications related to the prosthesis. Two extrusions, two implant migrations and a capsular contracture were reported, yet only two implants required explantation.

Isolated case reports of custom moulds for pectoral enhancement and pectus excavatum followed until Aiache described a subpectoral placement of soft silicone implants in males via a transaxillary approach. [35] Other authors also use this technique and stress the importance of not releasing the pectoral attachments to the chest, thus preventing implant migration inferomedially or laterally. [36] No breakdown of implant related complications, if any were provided.

Horn believed maintaining implant position was key to longstanding results and used textured, cohesive silicon implants for his cohort of male pectoral augmentation. [37] In twelve patients there was a subjective high patient satisfaction and no complications. [37]

A cohort of sixteen patients had no major complications following transaxillary pectoral implantation. [38] Three patients required drainage of a unilateral seroma. However there was no re-operation, capsular morbidity, infections or haematomas.

A more recent, larger cohort described the three typical presentations for pectoral enhancement; body builders with pectoral injuries and secondary asymmetry, hypoplastic pectoral deformity and those that cannot obtain the desired pectoral projection with regular exercise. [39] The authors described measurements to help aid implant size selection in those with a pectoralis major muscle (the majority). These measurements described were; infraclavicular width and height of the mid-portion of the muscle between the clavicle and its lower border, plus the distance between the axillary fold and the lateral edge of the sternum. The subsequent implant size and pocket is approximately two centimetres shorter than these dimensions. In 21 patients no complications were reported, however follow-up duration was not documented. Of interest it was the authors opinion that custom made implants, whilst a better “fit”, could be less desirable than textured cohesive implants for bodybuilder/athletic patients. Patients have reported dissatisfaction with pectoral implants because they can restrict exercise and intense exercise can displace implants. [40] There is no validated questionnaire or study to support this but it was felt custom implants are harder and restrict exercise whereas the textured prosthesis is more pliant.

There is a relative lack of study into male chest enhancement, most likely because it is not a common procedure. There are no large case series. The current literature would suggest it is a relatively safe procedure because few complications have been reported with subjectively high patient satisfaction.

UPPER LIMB AUGMENTATION

Upper limb enhancement is useful to restore symmetry where rupture or denervation of muscle has occurred. Deltoid enhancement following axillary nerve injury has been described. Custom-made silicone implants modelled on the contralateral normal deltoid contour were implanted. All implants were submuscular overlying the humeral periosteum/glenohumeral joint. The exact number of deltoid enhancements performed is unclear but no patients experienced any complications and follow-up totalled four years. [41]

The same author also enhanced an unknown number of biceps deformities by placing implants in a subbrachialis pocket. [41] Appearances at rest were reported as good by the operator but this tight submuscular pocket allows no implant movement and the dynamic movement of a visible biceps muscle cannot be recreated. No complications were reported although the total follow-up period was not stated. Chugay recently described placement of silicone implants in the sub-bicipital plane, through an axillary incision. [42] In the cohort of 94 patients there were three major complications: one seroma requiring serial drainage; one implant migration requiring revision surgery; and one compartment syndrome following concomitant biceps and triceps implantation. [42] There were two cases of medial antebrachial neurapraxia, but no infections, capsule morbidity or functional impairments were reported.

Triceps enhancement has been used to enhance size post-trauma and for individuals with poor muscle bulk. Hodgkinson found the medial head of triceps rupture in bodybuilders to cause significant asymmetry that cannot be corrected by exercise alone. [41] He described a distal arm approach through a transverse incision within the superior posterior elbow creases. [41] In cases of traumatic medial head rupture, the distal radial nerve is protected and the detached muscle fibres are removed medially, to make a sub-triceps space. Hodgkinson reported no infections, extrusions or capsule morbidity for a small undefined cohort. However, one patient experienced bilateral radial nerve neurapraxia (wrist drop). Calf implants were used in patients who were not posttraumatic. In contrast, Chugay used an axillary approach to create an implant pocket beneath the long head of triceps and now prefers a subfascial pocket in the posterior arm for tricep augmentation. [43] Fourteen patients had implantation of custom-made solid silicone prostheses. Two patients required revision surgery for implant migration and one patient experienced an ulnar nerve neurapraxia that resolved.

It is likely the number of upper limb enhancement procedures will increase in coming years given the global trend of males increasingly seeking cosmetic procedures. There is very little evidence measuring the effect, if any, that upper limb enhancement has on patients. Large series, possibly through collaboration, with meticulous reporting of adverse sequelae and validated patient outcomes will help determine the best surgical approach.

CONCLUSION

At present intramuscular gluteoplasty appears to have the most reproducible outcomes in terms of complication rate. Refinement of other techniques may enable the surgeon to be patient specific with the implant placement. In conjunction with this objective patient

satisfaction will be required in future series to accurately correlate, if possible, patient outcome and surgical approach and complication rate. The optimal site for calf implantation is not clear. Objective patient evaluation will aid the future direction of this surgery given that there are relatively low complications reported for the various planes of implantation.

The smallest cumulative experience exists for pectoral and upper limb enhancement. It is probable this group are the most heterogeneous given that many cases reported have a pathological cause for the alteration in body parts. Restoration of other body parts, such as the face following trauma/paralysis of muscle is common. We believe there is an element of taboo amongst surgeons and patients when offering/asking for prosthetic restoration of the upper limb or chest. Once this is overcome collaboration will hopefully concentrate experience and allow accurate assessment of outcomes and patient satisfaction.

Chapter 41

COSMETIC SURGERY IN THE ADOLESCENT PATIENT

Kelsey Larson^{*}, Sidhi Gosain[†] and Arun Gosain[‡]

Cleveland Clinic Foundation, Cleveland OH, US

KEY POINTS

- As the number of adolescent individuals seeking cosmetic surgical procedures continues to grow, it is important for practitioners to understand the unique considerations for this patient population.
- Since adolescents may still be completing their growth, it is important to consider the normal development of these individuals with relation to the surgical procedure at hand.
- More research is needed to understand what, if any, influence that surgery has on final stages of growth and development in adolescent patients. In addition, it is important to be upfront with patients on this uncertainty.
- Adolescents often require more in-depth screening and discussions preoperatively to determine appropriate candidates for surgery and to ensure patients, parents, and surgeons agree on reasonable, clear goals for the procedure.

INTRODUCTION

Adolescents (younger than eighteen years old) represent a small percentage of patients undergoing cosmetic surgery (approximately two percent) [1,2] with this percentage remaining steady over the last decade. However, as the total number of individuals seeking cosmetic surgery overall grows yearly (increasing by approximately six percent from 2010 to 2011) [1,2,3] so too does the number of adolescents seeking aesthetic procedures. While many European plastic and aesthetic surgical societies collect and report yearly data on

cosmetic surgery procedures, the most detailed European data readily available, reported by the British Association of Aesthetic Plastic Surgeons (BAAPS), [3] does not report by age group. Thus the exact number of adolescents presenting for cosmetic surgery in the UK or Europe as a whole is unclear. This data is available for the United States, however, and shows that around 230,000 adolescents had cosmetic surgical procedures in 2011, with approximately 76,800 of these (33%) being surgical operations (as opposed to minimally invasive/procedural) (Table 1). [1]

As the number of adolescent individuals seeking cosmetic surgical procedures continues to grow, it is important for practitioners to understand the unique considerations for this patient population. This chapter, expanded from a previously-published paper, [4] seeks to provide information on psychological considerations and cultural influences affecting adolescents presenting for plastic surgery; procedure-specific considerations for the most commonly performed operations; and comment on patient selection and trends relating to adolescents. For the purpose of this chapter, specifically surgical operations (not minimally invasive office-based procedures) will be addressed.

When considering the number of surgeries noted throughout this chapter, it is important to remember that the data presented represents a select group of societies that report patient statistics in readily available format. However is in no means inclusive of all adolescent patients who present to surgeons for consideration of cosmetic surgery, or even of all teens who undergo cosmetic procedures.

Table 1. Estimation of cosmetic surgical procedures in one year. ASPS [1] data for all age groups (total) and 13-19 year age group (teen). BAAPS [3] and ISAPS [5] data reflects total procedures performed across all ages, neither organisation providing data divided by age group

	ASPS (teens)	ASPS (total)	BAAPS	ISAPS
Rhinoplasty	33,892	243,773	4,518	985,325
Breast Augmentation	8,892	307,180	10,015	1,506,475
Breast Reduction	*	*	4,501	549,994
Gynaecomastia	14,371	19,766	790	235,947
Chin Augmentation	1,809	20,680	**	108,178
Blepharoplasty	1,881	196,286	6,057	1,085,153
Liposuction	3,248	204,702	3,581	2,174,803
Otoplasty	7,489	26,433	1,170	242,271

*ASPS does not report breast reduction numbers for cosmetic versus reconstructive patients. However, ASAPS [2] indicates 2,944 patients <18 years old and 112,964 patients across all age groups underwent breast reduction.

**Unlisted in BAAPS data. (ASPS - American Society of Plastic Surgeons;

BAAPS - British Association of Aesthetic Plastic Surgeons;

ISAPS - International Society of Aesthetic Plastic Surgeons;

ASAPS - American Society of Aesthetic Plastic Surgery).

PSYCHOLOGICAL CONSIDERATIONS

Body Image Development and Relationship to Cosmetic Surgery

Understanding and addressing body image with adolescent surgery patients is a critical component of interacting with this group of individuals. During puberty especially, significant transitions in the patient's physical appearance and interest in peers' opinions leads to major changes in body image. Body image, the "subjective perception of the body as it is seen through the mind's eye," [5] was first described by Schilder in the 1930s. [6] He postulated that overall life satisfaction, body image, and self-esteem combine to influence a person's confidence and outlook on life. Recent work on the connection between body image and cosmetic surgery centres on four basic principles: the physical reality of appearance, the perception of appearance, the importance of appearance, and the degree of dissatisfaction with appearance. [7] These concepts form a continuum of body image satisfaction, from overly-assured or arrogant about oneself to pathologic dissatisfaction such as with body dysmorphic disorder (BDD). [8] A complete review of cosmetic surgery patients, body image, and body image development in adolescents is outside the scope of this chapter; however, it is important to consider where on the spectrum of body image satisfaction each adolescent patient lies when selecting an appropriate candidate for surgical intervention.

In the past, both proponents and opponents of cosmetic surgery in adolescents have used the rapid change in body image to argue their opinion on the topic. In the 1980s, a Dutch study demonstrated linear improvement in body image as adolescents grow up, regardless of cosmetic surgery status. [9] This *idea of improvement in body image with age without surgical intervention* was initially a leading piece of data which opponents of adolescent cosmetic surgery used in evaluation patients and conducting further research. However, more recent data found that the improvement in body attitude in adolescent cosmetic surgery patients exceeds the previously reported natural improvement in body image as the patients aged. [10] Teenagers in the cosmetic surgery group postoperatively reported significant decrease in appearance-related burdens and significant improvement in self-image compared with non-surgical controls.

Opponents to cosmetic surgery for teens also argued that teenagers were presenting with unrealistic concerns for their appearance and thus surgical intervention would be counter-indicated. To address this concern, researchers published a study in the British Journal of Plastic Surgery demonstrating that adolescents presenting for consideration of cosmetic surgery had a realistic view of their body compared to the assessment of the parent and surgeon. [11] Furthermore, parents and teens had similar assessment of the psychological and social burdens relating to the cosmetic concern, and surgeons confirmed realistic/reasonable flaws in these adolescents. Additional studies have demonstrated no difference in self-confidence or mental health measures when comparing teenagers presenting for cosmetic surgery versus age-matched controls, but rather demonstrated specific dissatisfaction with a particular aspect of their physical appearance. [9,12]

Plastic surgeons need to continue strict screening of their patients (see "Patient Selection" discussion later in the chapter) including screening for pathologic body image disorders. The ongoing body image development of adolescents presenting for cosmetic surgery should be

considered, but evidence indicates that this factor alone should not be a deterrent to considering surgical options for them.

Gender Considerations

Many speculate that adolescent girls and boys presenting for cosmetic surgery have different goals for surgery and/or different postoperative satisfaction. In adults, male cosmetic surgery patients account for approximately ten percent of procedures performed; it is likely this number is larger in the adolescent population given gynaecomastia operation in boys alone already accounts for eighteen percent of total cosmetic surgeries in 13-19 year-olds. [1] Studies specifically addressing male versus female adolescent patients note that boys were overall more satisfied with their appearance, but that girls' appearance evaluation tends to naturally become more positive over time (versus boys' appearance evaluations which tend to remain the same). [13] Evaluation of adolescents following cosmetic surgery demonstrates no significant differences in postoperative satisfaction (92% for girls versus 80% for boys) and low rate of desire for additional surgery with the majority of patients reporting very good (60.5%) or good (33.3%) results. [14] More studies are needed to fully elicit the differences, if any, between adolescent girls and boys who present for cosmetic surgery.

CULTURAL INFLUENCE

Sociocultural attitudes towards appearance questionnaires-3 (SATAQ-3) around the world support the intuitive notion that adolescent females are tremendously affected by cultural ideals of beauty. [15,16] Why the obsession? As Freud put it, "the enjoyment of beauty, has a peculiar, mildly intoxicating quality of feeling. Beauty has no obvious use - yet civilization could not do without it." [17] Though cultural standards may differ, there appears to be a universal hierarchy in which beauty is one's key to upward mobility.

Studies done internationally indicate that biologically-based factors such as averageness, symmetry, and sexual dimorphism influence attractiveness, but experience and, consequently, familiarity do as well. [18] This technical research explains why not many people prize their unique noses as an emblem of individuality and instead view them as a hindrance to social acceptance. Therefore the primary aim of cosmetic surgery across cultures entails a dichotomy that is particularly influential during the psychosocial development of the adolescent years. Individuals wish to "fit in" while simultaneously standing out in features they believe will be perceived positively by their peers.

What cultures across the globe do not share, however, is the conventionally American inclination towards "quick fixes" in the pursuit of happiness. Several hospitals around the world have implemented their own version of psychological screenings that must be "passed" in order for the patient to undergo cosmetic. [19] However, the subjectivity of these screenings suggests that the validity of the parameters being screened may be of questionable validity. At this time, a validated, easy to administer psychological survey is unavailable to practitioners. Each surgeon's screening methods vary greatly, establishing the possibility of inconsistent conclusions as to the psychological status of patients. Further research to build a

universal, validated, easy to administer survey is ongoing and would help create objective assessments for those countries that use psychological screening routinely for their patients.

While no study can truly represent the view of an entire continent (i.e., the “European look”) or even a nation (i.e., the “French look”), international media aids in revealing general beauty trends and how a similar look might be acquired. In the words of French actress Juliette Binoche (at the 2010 Cannes Film Festival):

“In France, beauty is much more subtle...we think it’s more about looking after yourself than going down the artificial route.”

In addition, although he does mention the “booming” of the cosmetic surgery industry in France, Parisian plastic surgeon Bernard Mole says “The aesthetic goals of cosmetic patients in France are geared towards more subtle changes (than those in the United States)”. [20] Debra Ollivier, an American author who married and raised two children in Paris, agrees. In her book, [21] she explains how in France, peculiarities tend to be valued over conformity with respect to aesthetics, as they preserve an individual’s uniqueness and personal flair. While beautiful models are still prized at face value, they have not gathered a following comparable to that in the U.S., where their admirers are often willing to undergo surgical procedures in order to emulate these models. [21] This difference may in part be due to the economic affluence of the U.S. combined with family values that accept appearance to be an essential factor for success.

More cultural factors exist behind differing psychology of cosmetic surgery patients. A 2009 study in Norway found that both education and quality of relationship with parents were negative predictors of cosmetic surgery in young women. [22] The same study listed being teased as a positive predictor of cosmetic surgery. According to Debra Ollivier, the French family unit is very tight-knit, while its American counterpart is better described as “dysfunctional”. [21] This comparison may provide further insight as to why teenagers in America opt to change their looks as opposed to modifying behaviour or developing other skills that may help them to succeed. Once again a “quick fix” is employed in an attempt to ameliorate a situation; if strong parental bonds do not exist, teens may turn to cosmetic surgery to fit in with peers.

Adolescents’ hopes and primary objectives of cosmetic surgery, however, seem to be more or less the same across the globe: improved body image and self-esteem, which in turn usher forth higher social status and quality of life. [23] While looks are by no means a final marker of potential to succeed in life, it is impossible to remove society’s affinity for the aesthetically blessed.

Youths who are teased for being ugly are unlikely to apply themselves in school or otherwise; meanwhile, those at the opposite end of the spectrum might not apply themselves because of their preoccupation with themselves, not realizing that their looks may one day fade as well.

The central dilemma cosmetic plastic surgeons continue to face is where to set the limit on what operations will benefit the patient enough to outweigh the emotional, financial, and any ethical costs that may accompany cosmetic surgery performed in adolescents.

PROCEDURE-SPECIFIC CONSIDERATIONS

Since adolescents may still be completing their growth, it is important to consider the normal development of these individuals with relation to the surgical procedure at hand. Details of each operative procedure can be found in the corresponding chapters of this textbook, with the following discussion aimed at specific considerations in adolescents.

Nasal

Rhinoplasty is one of the most common cosmetic procedures performed world-wide, with international data estimating rhinoplasty to be the fourth most common cosmetic procedure, [24] British data estimating it to be the fifth most common cosmetic procedure (approximately 4500 operations) [3] and American (ASPS) data estimating rhinoplasty to be the second most common cosmetic procedure. [1] Importantly, ASPS data demonstrates rhinoplasty is consistently the most common procedure in thirteen to nineteen year-olds, accounting for approximately 44% of cosmetic surgeries performed in this age group.

Nasal growth continues up to the age of eighteen years when the overall facial growth is complete. [25] The various components of the nose develop from their own unique embryologic origins [26] with numerous possibilities for congenital malformations. [27] In general, periods of slower and faster changes occur along a similar timeline as overall body growth of the individual. The authors recommend consideration of cosmetic rhinoplasty in girls from thirteen years or in boys from fifteen years of age, as the nose has completed approximately 90% of its development by this time.

When addressing rhinoplasty in adolescents, surgeons must take into account the critical nasal components, specifically the lacrimal bone and enclosing sutural tissue. This area is the single growth centre that should not be disturbed before nasal development is complete as it is primarily responsible for stabilizing the horizontal and vertical growth of the nasomaxillary complex. In general, nasal osteotomies are contra-indicated until after sixteen to eighteen years of age for the above reason.

While there has been limited information on rhinoplasty under twelve years of age, [28] multicentre studies with large patient numbers and long follow-up for complete assessment have not been done. Numerous publications with recommendations for rhinoplasty to correct severe functional difficulties or posttraumatic injuries in children focus on restoring anatomic relationships, especially of the septum, to promote wound-healing and normal development. [29,30,31] These authors also promote open over closed rhinoplasty in an effort to preserve, as much as possible, the integrity of the cartilaginous skeleton.

With respect to purely cosmetic rhinoplasty, limited data is available as most surgeons recommend waiting until after the completion of facial growth before proceeding to surgery. Chauhan et al. [29] has published the most complete paper detailing not only the surgical changes but also the psychosocial considerations for adolescents undergoing aesthetic nasal surgery. This group recommends avoiding elective rhinoplasty until the following criteria can be met: at least one year after menarche for women, stable growth of the individual for a minimum of one year, psychological readiness, and parental support. This study's use of validated questionnaires to assess overall, social and health-related benefits, combined with a

follow-up of three years with good results, provides the strongest assessment of adolescent rhinoplasty. Patients in this study were between thirteen and nineteen years old, with a mean age of seventeen years, in line with previously stated age guidelines.

Breast

Breast development during puberty typically begins between the ages of nine and thirteen years old in girls, with average age in multiple studies in various countries around twelve or thirteen years old. [33] The stage of development, determined by the Tanner staging system, clearly defines the clinical process. Stage 5, completion of development, is characterised by breast reaching final adult size, the areola returning to contour of surrounding breast with a central papilla extending slightly above contour. Fourteen years old is the most common estimate of the age of Tanner stage 5, with ranges from twelve to sixteen years old. [34] Complete and final breast growth and development, however, can persist into a woman's early twenties.

Breast Augmentation

Breast augmentation is the second most common procedure performed worldwide, [24] and the most common cosmetic surgery procedure in Britain [3] and the US [1] each year. ASPS data indicates it is the third most common aesthetic surgery in adolescents, accounting for approximately 11.5% of all cosmetic surgery procedures on those thirteen to nineteen years old. [1] Of those in this age group who undergo breast augmentation, 44% is for purely cosmetic reasons. [2]

In the US, saline implants for purely cosmetic breast augmentation are approved by the FDA for women eighteen years and older, while silicone implants are approved for women 22 years of age or older. [35] Younger individuals may have these implants placed for cosmetic augmentation, but this would be considered an "off label" use for the implants. If the augmentation, however, is for reconstruction (tuberous breast deformity or Poland syndrome), either style of implant is then considered approved by the FDA. Age limitations are imposed due to the theory that breast development continues into the early twenties and due to maturity concerns relating to informed decision-making. In Europe, definitive age recommendations regarding approval for breast augmentation is not as strict as in the US.

For all young women, it is important to be upfront with patients regarding the unknown effect of cosmetic breast augmentation on further development and future breast health. Specifically, patients should be informed that long-term follow-up studies of women who undergo cosmetic breast augmentation as an adolescent are not available. Data extrapolated from adult breast augmentation patients may or may not be applicable. In addition, adolescents should be clearly informed of the life span of breast implants, typically quoted about ten years, and the likely future need for re-operation (replacement, adjustments, or removal) given the young age at initial operation.

Breast Reduction

Breast reduction is the sixth most common cosmetic surgical procedure throughout the world, [5] third most common in Britain [3] and ninth most common in the US. [2] Reduction

is a bit of a grey area in terms of breast surgery, sometimes being classified under cosmetic or aesthetic operations and sometimes under reconstructive operations. Often reduction is accompanied by a breast lift for improved cosmetic outcome, with inclusion of these patients again changing the number and percentile of reported procedures. Breast reduction accounted for just fewer than three percent of the total cosmetic surgeries performed on under eighteen year-olds in the US. [2]

Typical patients presenting for discussion of breast reduction note complaints such as back or neck pain, worsening body posture, dermatitis or other skin irritations under their breasts, shoulder indentations from bra straps, and limitation of physical activity. Following breast reduction, studies have demonstrated improved psychological scores for women in the areas of body image, self-esteem, and relationships. [36,37,38,39]

Despite numerous studies demonstrating benefits in patients undergoing breast reduction, there is limited evidence on adolescents who undergo breast reduction. Small series indicate mammoplasty is well tolerated in teenagers with normal or elevated BMIs with low reported complications. [40] Sustained relief of symptoms for several years has been reported in limited patient populations. [41,42] However, as with breast augmentation, long-term follow-up of teenagers who undergo breast reduction and its effect on development, need for future surgical intervention, and lasting effect of relief of symptoms has not been completely explored. In the author's limited experience with breast reduction in adolescents, patients do, at least initially, report definitive relief of symptoms.

Gynaecomastia

Surgical treatment for gynaecomastia was the tenth most common cosmetic surgical procedure world-wide, [5] second most common in British men [3] and fourth most common in US men. [1] Even more importantly, it was the second most common cosmetic surgical procedure performed on thirteen to nineteen year-olds in the US, accounting for almost nineteen percent of aesthetic operations in adolescents. [1] This number is likely underestimated given that paediatric surgeons and breast surgeons who report in different databases are also performing these procedures.

Adolescents presenting for discussion of surgery are often obese or overweight, although almost one quarter of patients have causes other than weight-related factors as an explanation. [43] It is recommended that adolescents who present with gynaecomastia during puberty are observed for six to twelve months since further growth and/or weight loss can affect body contour and the relative prominence of the breast. However, should gynaecomastia persist beyond this period of observation and affect the self-esteem of the child, surgical intervention should be considered. Often adolescents with gynaecomastia are so troubled by their figure that they are reluctant to participate in sports or change in public locker rooms so that their deformity is not noticed by their peers, making weight loss even more challenging. Understandably, obese adolescents require more extensive operations, but are equally satisfied and have similar postoperative complications rates as their average weight counterparts. [24] The majority of patients (approximately 75%) undergo bilateral surgeries with peri-areolar skin incisions and bipedicle techniques to minimise nipple-areolar complex necrosis. [24,44,45,46] Most articles report almost 100% satisfaction rates postoperatively, although extensive postoperative follow-up using validated questionnaires is missing. One study noted about twelve percent of individuals contacted postoperatively were "not satisfied"

but details as to what contributed to postoperative dissatisfaction were not provided. [25] In contrast to many studies in adolescents, adults with gynaecomastia are usually a difficult patient population to please. This difference in satisfaction postoperatively is unclear, and likely represent a combination of the limited studies in adolescents, the psychological differences between adults and adolescents, and the primary reasons for desiring surgery in the first place. In the authors' experience, young men who seek surgery have experienced ridicule regarding their appearance and report very positive changes in postoperative self-esteem and confidence.

Similar to young women presenting for breast surgery, it is important to counsel young men presenting with gynaecomastia as to the limited long-term follow-up data for corrective surgery. It is unclear what effect, if any, such surgery has on further development. During the operation, the most important point is to ensure as complete removal of breast tissue as possible. Any tissue left behind could grow in the future leading to recurrence of the original condition or area of concern. Overall, life-long recurrence rate specifically for adolescents who undergo cosmetic surgery for gynaecomastia is unknown, and long-term patient satisfaction has not been studied.

Chin

Chin augmentation is less common than previously discussed cosmetic surgical procedures, only fourteenth most common internationally [5] and is not listed as one of the most common cosmetic surgeries in the BAAPS audit. [3] ASPS data also indicates mentoplasty as a relatively uncommon procedure, accounting for only two percent of thirteen to nineteen year-old cosmetic surgery patients. [1] These numbers represent purely cosmetic mentoplasty and exclude those patients with developmental conditions such as craniofacial microsomia who have specific underlying pathologic conditions. Individuals with these conditions are best addressed via evaluation with a team-based approach including paediatric craniofacial surgeons and orthodontists who can address the complex nature of patients' situations.

Given the small number of adolescents each year who undergo simple cosmetic-driven mentoplasty, the paucity of published material on this topic is not surprising. Final growth of the mandible, similar to the rest of the facial skeleton, continues until a person's mid-teenage years. In the authors' opinion, mentoplasty using chin implant provides a safer alternative than sliding genioplasty in adolescents as their facial features are still undergoing some final development. Over the late teenage and early twenties, the optimum chin shape and projection for the individual's face is likely to change slightly as he or she undergoes further maturation into adulthood, and implants allow for easier repeat operations for fine-tuning at an older age compared to the more permanent sliding genioplasty.

Eye

Blepharoplasty is the third most common cosmetic surgery around the world, second most common in Britain [3] and fourth most common in the US. [1] However, in adolescents thirteen to nineteen years old, blepharoplasty is relatively uncommon, representing only two

percent of cosmetic surgeries in this age group. [1] While the exact characteristics of these patients has not been published, adolescent blepharoplasty patients tend to have a history of craniofacial deformities or traumatic injuries which lead to soft tissue deformities requiring correction. Indication for purely cosmetic blepharoplasty in one's teen years without underlying craniofacial or traumatic aetiologies is unusual.

Body

Liposuction is the most common cosmetic surgical procedure on an international basis, [5] sixth most common cosmetic surgical procedure in Britain [3] and third most common in the US. [1] Many would be surprised that liposuction is the fifth most common cosmetic surgery in thirteen to nineteen year-olds, although this is only four percent of procedures in these adolescents. [1] Similar to adults who present requesting liposuction, adolescents should be evaluated for their understanding of the goals of the procedure (to improve contour and minimise disproportionate areas) and the understanding of what the procedure cannot accomplish (significant weight loss in obese individuals). It is important to re-enforce to adolescents that the procedure is not a substitution for a well-rounded diet and exercise, and further encourage these healthy habits at a young age. Good adolescent candidates for liposuction are those with a specific area of unnatural and/or asymmetric fat deposition, especially if it is interfering with activity level or lifestyle. Similar to adults, teenagers who continue to have excessive fat deposits despite demonstrating a commitment to exercise and appropriate eating are stronger applicants for surgical intervention. For the typical adolescent patient who presents for discussion of liposuction, lifestyle changes should take precedence over surgical intervention.

Otoplasty

Otoplasty is the ninth most common cosmetic surgical procedure on an international basis [5] and the tenth most common cosmetic surgical procedure in Britain. [3] However, adolescents make up a significant number of the total patients undergoing this procedure, with approximately 7400 operations on US adolescents in 2011, accounting for 28% of total procedures on this age group. [1] In the United States, otoplasty is increasingly viewed by insurance carriers to be a cosmetic procedure as opposed to correction of a congenital deformity. In the author's practice of plastic surgery in the paediatric and adolescent population, otoplasty and correction of gynaecomastia are the procedures most commonly not routinely covered by insurance carriers.

Secondary Cleft

Adolescents with secondary cleft deformities represent a unique subset of patients presenting for discussion of rhinoplasty and/or lip revisions. These patients do not fit clearly into the cosmetic surgery category as their area of concern stems from a primary developmental problem, but many no longer consider surgery for secondary cleft deformities

reconstructive as the primary cleft problem has already been corrected. In the US, more of these adolescents are meeting resistance from insurance companies when they present for rhinoplasty or other surgical procedures to correct aesthetic concerns.

Previous studies evaluating the overall psychological status of cleft lip/cleft palate patients have found increased rates of depression and anxiety as adults, [47,48] elevated concern for abnormalities in nose and dentition, [28] problems with body image, and lower self-confidence. [49] Surveys of adult patients demonstrate that those who did not seek secondary treatment reported lower quality-of-life scores with almost 63% of women surveyed expressing desire for further correction of upper-lip and nose concerns. [50,51]

While numerous researchers have attempted to follow-up with patients using a variety of questionnaires, [52] it has not been until recently that a focused, validated survey specifically addressing the unique concerns of cleft lip / cleft palate patients has been developed. Klassen et al. [53] have begun to develop a CLEFT-Q - a validated quality of life questionnaire for cleft lip / cleft palate patients similar to that of the BREAST-Q in place for breast surgery patients. [54] Research which follows from this questionnaire will provide further insight into adolescents dealing with these conditions, and will serve as an example of projects which are needed to address aesthetic adolescent surgery in general.

PATIENT SELECTION

As in all areas of cosmetic surgery, patient selection and preoperative evaluation/assessment is of utmost importance. The American Society of Plastic Surgeons suggested points to consider when evaluating an adolescent presenting for cosmetic surgery (paraphrased below) [55], with further details provided in the authors' opinions.

Patient Is the Primary Person Who Desires Surgery and Initiates Discussion

As surgeons assess whether or not a request is medically appropriate, they should also ask why the individual is interested in the procedure. Adolescents who indicate that a family member or friend has suggested cosmetic surgery but do not clearly state why they want the procedure for themselves are at risk of regretting the decision or being unhappy with results.

Further, patients who acknowledge internal motivators tend to be more in touch with their sense of self, demonstrate more maturity, and be happier with outcomes. Examples of internal motivators include ideas such as "I would be more confident if I was not worried about the appearance of my nose" or "I would be much happier and less critical of how I look in photos." Examples of external motivators include ideas such as "I would become more popular" or "Boy/girls would like me more." Internal goals relate to sense of self and body image and tend to be reasonably met following surgery. One can understand how, if a person is less preoccupied with a perceived flaw, he or she will demonstrate more confidence. However, external goals are often unreasonable to achieve as they rely on obtaining the approval of others. Postoperatively, when a more streamlined nose does not lead directly to the popular crowd, the patient is likely to be disappointed and hypercritical of the surgical outcome. Whereas assessment of motivators can be applied to many cosmetic surgical

patients, this assessment is even more crucial when evaluating the adolescent patient. Adolescents are at a particular time of their life where external motivators tend to be more highly valued and the opinion, or presumed opinion, of others tends to be held in higher regard.

Patient Has Reasonable Goals, and Understands the Benefits and Risks

Adolescents with a clear, defined request and reasonable goals are more likely to be satisfied postoperatively than those teenagers with vague expectations. A young woman concerned over a hump in her nose and requesting a more linear profile provides a surgeon with a clear goal when counselling, discussing outcomes, and reviewing risks/benefits. On the other hand, a teenager requesting a “cuter nose” does not give a clear picture of her expected outcome. Often adolescent individuals have a more difficult time articulating their exact concern compared to their adult cosmetic surgery counterparts. It is thus important to spend additional time with these individuals to make sure that patient, parents, and surgeon are on the same page prior to proceeding to surgery. Teenagers often require multiple appointments to fully explore the surgical risks/benefits, give accurate information on how they want their appearance to change, and ensure that all questions have been answered.

Adolescents tend to see circumstances in black and white more so than adults, with outcomes viewed as perfect or disastrous. It is the surgeon’s job to clearly define what will happen pre- and postoperatively and to be exceptionally honest with the patient as to whether or not their goals can be achieved. Plastic surgeons have a responsibility to turn down cosmetic surgical requests from teenagers especially if they do not feel the goals of the patient can be met or desired outcomes from the procedure can be reasonably achieved.

Patient Demonstrates Maturity Toward Decision Making and Dealing with Postoperative Discomforts or Less Than Perfect Outcome

The initial assessment of adolescent maturity comes with the above patient interactions. At the very minimum, the teenage patient should be able to calmly and sensibly have the above discussions with his or her parent and surgeon, including dealing with questions or concerns that arise. Surgeons also need to explore how the adolescent will cope with postoperative discomfort, complications, or poor outcomes. This issue can be addressed with direct questions (“How will you handle peers who notice you look different?” or “How would you deal with this complication?”) or with indirect links (“What is a difficult situation you’ve been in, and what did you do to resolve it?”). The questions not only allow the surgeon to assess the teenager’s maturity, but also encourage the patient to consider in advance how he or she would deal with possible postoperative issues and hopefully initiate a discussion between the patient and parent on such a topic.

As part of a routine preoperative work-up, a psychological history should also be obtained. Anyone with a known psychopathologic condition or anyone the surgeon is concerned about coping with postoperative difficulties should be evaluated by a psychologist or psychiatrist prior to surgical intervention, with postoperative care and follow-up coordinated with this support system as well.

TRENDS IN COSMETIC SURGERY IN ADOLESCENTS

In the past several years, the number of cosmetic plastic surgery procedures has increased by approximately five to six percent overall from one year to the next [1,3] with teenagers steadily accounting for about two percent of this total year by year with increasing gross numbers in keeping with those of the adult cosmetic surgery population. Of the most common cosmetic surgery procedures in this age group, rhinoplasty, breast augmentation and gynaecomastia surgery have remained approximately steady in terms of numbers with the same ranking of popularity of procedures.

Reasons why more adolescents are seeking cosmetic surgery are beginning to become evident as researchers focus more attention on this specific group of individuals. Survey results of high school students demonstrate that two thirds of students knew someone who had undergone cosmetic surgery but only one third would be interested in such surgery for themselves. [56] Interest was most commonly expressed in liposuction, rhinoplasty, breast augmentation and breast reduction, somewhat in keeping with the popularity of procedures reported in annual statistics. Importantly, teens who expressed interest in aesthetic procedures described cosmetic surgery patients as “motivated,” while those who did not express interest felt these patients were “vain.” Not surprisingly but unfortunately, 96% of high school students surveyed reported primary source of information on cosmetic surgery as magazines or television rather than physician or other health-care source. Similar survey results from college-age students illustrate the link between greater internalization of mass media images of beauty and more positive attitudes toward aesthetic surgery. [57]

As adolescents become increasingly ensconced in the digital era, media, marketing and associated celebrities are more commonly encountered each day via the ever-increasing use of the Internet, social networking sites, smart phones and other digital devices. Numerous studies have demonstrated a link between more intense celebrity admiration and drive for cosmetic surgery procedures, [58] with experts suggesting a link to ever increasing unrealistic societal beauty ideals. [59] As noted in the above study, magazines and television are the main sources adolescents use to learn about cosmetic surgery, so with increasing mainstream information via these resources, more and more teenagers are likely to consider aesthetic surgery. In addition, as the number of procedures rises each year, more postoperative patients are discussing cosmetic surgery with their peers, generating further interest. Minimally invasive procedures are also becoming popularised, making prior deterrents from surgery (scar formation, pain, longer recovery) less important considerations.

CONCLUSION

It is clear that in the coming years, the total number of individuals seeking cosmetic surgery will continue to increase, and along with it the number of adolescents requesting such procedures. Plastic surgeons must understand that these individuals are not just small adults, as is often quoted in paediatric surgery, but also that they have specific psychological and developmental concerns unique to their age group. Going forward, additional research is needed to understand the effect of surgery on end-stages of growth and development into adulthood and the long-term outcomes obtained from procedures during the adolescent years.

Chapter 42

HAND REJUVENATION

Kuen Chin^{1,*} and Fulvio Urso-Baiarda²

¹Ninewells Hospital, Dundee, UK

²Wexham Park Hospital, Slough, UK

KEY POINTS

- It is possible to judge a person's age based solely on the appearance of their hands. This combined with the increasing popularity of facial rejuvenation may have resulted in the observed increase in requests for hand rejuvenation in recent years. The overall evidence basis for these procedures is scant.
- Features of ageing hands include skin laxity, actinic skin changes, soft tissue atrophy and the development of venous prominence. Rejuvenation modalities may address some or all of these.
- No modalities addressing skin laxity are supported by strong evidence. The least invasive modality is medical needling, which has a good safety profile when used elsewhere but lacks safety and efficacy data for use in the hand.
- Venous prominence has been addressed by sclerotherapy and endovenous laser therapy, neither of which is backed by strong evidence. From what literature is available their efficacy seems similar, but laser treatment may have a more favourable safety profile.
- In contrast to the other treatment modalities, volume enhancing hand rejuvenation treatments are supported by reasonable evidence. Autologous fat grafts appear to survive at least into the early (five month) postoperative period, after which one would expect longer-term survival from our experience elsewhere. There are few studies directly comparing non-autologous fillers, but HA appears to be most consistently favoured in terms of safety and efficacy.
- Fractional photothermolysis and Plasma Skin Resurfacing are the modalities targeting actinic skin changes of the hands that are supported by the highest quality

* Corresponding Author's Email: andycky@doctors.org.uk.

evidence (a single Evidence Level 2 study each). These small studies have demonstrated safety and short-term efficacy but no follow-up data beyond three months exists for either modality.

- Many authors have provided anecdotal reports of the use of combination therapies for hand rejuvenation, which appears to be a popular practice, but it has not yet been the subject of a high quality study.

INTRODUCTION

There has been much interest in hand rejuvenation in recent years. The discrepancy between the apparent age of a celebrity's hands and that of their face is the subject of regular media broadcasts. In a single year, one newspaper published the headlines: "Why do Madonna's hands look older than her face?" [1], "Even with muscles like these, Madonna can't beat the hands of time" [2] and "She's so vein... Madonna's hands look worse than ever" [3]. Whether cause or consequence, such articles reflect increasing preoccupation with senescent hands and how to disguise them.

Several authors have speculated as to why the hands might attract such attention. They are the second most exposed body part after the head and neck [4], making them both socially visible and highly susceptible to environmental and sun-induced ageing [5-7]. The ability of untrained observers to estimate age just by looking at a pair of hands [8] could readily subvert an individual's efforts to disguise the sequelae of facial ageing.

Whatever the origin for the demand for hand rejuvenation, a market has sprung up to supply it and, according to some sources, has more than trebled in recent years [1,9]. Although practitioners offer a plethora of hand rejuvenation procedures, their evidence basis is not always clear. This chapter aims formally to review the current literature and assess levels of evidence for current practice, to identify consensus opinion (both positive and negative) and those areas that warrant future investigation.

To do this, publications looking at hand rejuvenation procedures were identified with a PubMed search of the term: (*"Esthetics"[Mesh] OR "Rejuvenation"[Mesh]*) AND *"Hand"[Mesh]* (searched March 2012). Hits were filtered for relevance and their citation lists manually searched, until no more relevant articles could be found. Papers were assigned a level of evidence (LOE) derived from the American Society of Plastic Surgeons (ASPS) Scales for Rating Levels of Evidence.

OVERVIEW OF THE LITERATURE

The literature search yielded 191 hits, of which 29 were relevant to hand rejuvenation and another 28 identified manually from their citations. Eight of those were excluded as they were not peer-reviewed [10-14], not in English [15] or were unobtainable [16,17].

The 49 included publications consisted of those considering normal hand aesthetics and/or the changes that take place in ageing [5,8,18,19], complications of hand rejuvenation [20] or various hand rejuvenation modalities. The latter consisted of modalities addressing

skin excess, venous prominence [21-26], volume loss [7,27-41], skin quality [42-48] or a combination of those features [6,49-55].

THE AGEING HAND

Bains and co-workers [8] analysed factors contributing to a young or old hand appearance by comparing the age attributed to images of female hands before or after digital manipulation of features such as veins, blemishes, wrinkles makeup and jewellery. They found that an observer could accurately estimate age from isolated images of hands and that old hands were characterised by wrinkles, veins, prominent joints, thin skin, deformity and spots. Conversely young-appearing hands exhibited tissue fullness and a lack of veins or wrinkles. The single most ageing factor was the appearance of veins. Added nail varnish or jewellery could not disguise old-looking hands.

These findings were generally supported by a subsequent observational analysis of age-related changes in the hands [5] (LOE-4), except that tortuous veins were considered a better marker of ageing than veins per se, since athletic hands could display prominent (but straight) veins whilst remaining youthful and attractive. The study also found a gender difference in the ideal hand aesthetic, with most women preferring their non-dominant hand but most men preferring their dominant one. The authors speculated that this could reflect a more general difference between the sexes in preferring slenderness or muscularity. It is an important finding since most studies assessing patient satisfaction after hand rejuvenation have a mostly or wholly female subject population, and results may not be applicable to men.

Most studies addressing hand rejuvenation therapies use quantitative or semi-quantitative outcomes, but Carruthers [18] (LOE-3) wanted to make assessments of hand ageing more objective by defining a photonic rating scale (Table 1). To validate it, images of different aged hands were independently rated, and the inter- and intrarater agreement was found to be good. Surprisingly though, there was no attempt to correlate the scale with the actual age of the photographed hand, the scale only considered changes related to soft tissue loss, and the researchers stated that it had been validated for photographic but not live hand assessments. Those limitations would significantly impact the usefulness of the scale, and it does not appear to be in widespread use.

Table 1. Five-point photonic rating scale (modified from Carruthers 2008)

0	no loss of fatty tissue
1	mild loss, slight visibility of veins
2	moderate loss, mild visibility veins & tendons
3	severe loss, moderate visibility of veins and tendons
4	very severe loss, marked visibility of veins and tendons

In a literature review addressing normal hand aesthetics, Jakubietz and colleagues [56] concluded that normal anatomy and proportions were prerequisites for beauty, and that a long slender hand was generally considered elegant and beautiful. Consistent with earlier work, prominent veins could be considered attractive in male hands but less prominent vasculature was preferred in females. A youthful appearance was also attractive, and ageing could be

classified as extrinsic or intrinsic (Table 2). Procedures that reversed either type of ageing could rejuvenate hands and therefore beautify them.

Table 2. Signs of extrinsic and intrinsic hand ageing (Jakubietz 2005) [56]

Extrinsic ageing	Intrinsic ageing
Actinic keratosis	Wrinkles
Solar lentigines	Dermal atrophy
Punctate hypopigmentation	Fat atrophy
Solar purpura	Visible colour of tendons
Grouped, flesh-coloured papules	Prominent veins
	Visible bony contour

HAND REJUVENATION MODALITIES

Rejuvenation options for the hand can be divided into those addressing skin changes (either skin excess or photoageing), protruberant veins or soft tissue atrophy [50], any of which may be present to varying extents.

a) Skin Excess

The ‘distal dorsal superior extremity plasty’ was described by Wendt in 2000 [4] (LOE-4). It is a technique that aims to improve hand contour by excising ‘redundant’ skin from the dorsum via a transverse skin excision. Resectable skin is marked as an ellipse centred over the dorsal wrist crease with the wrist fully flexed, and the procedure is performed under local anaesthetic. Risk of transection of the dorsal branch of ulnar or superficial branch of radial nerves was pointed out by the author, although no complications were reported in the very small series (six procedures in two patients) and the need for multiple procedures per patient was not accounted for. Others have commented that such an approach could have a paradoxical pro-ageing effect by making veins and tendons appear more visible [31], and safety in terms of nerve injury, long-term scar stretch and stiffness have not been determined in any large study.

The technique has been modified recently [57] (LOE-4) to limit the scar to the ulnar side of the dorsum. The excess skin identified using the pinch test is marked in the dorsal carpal region preoperatively. Under local anaesthetic, intravenous sedation and tourniquet control, a flap is mobilised along a vector line between the second metacarpophalangeal joint and the caput ulnae. The author stressed restricting the extent of undermining to the ulnar and middle third of the dorsum as more extensive undermining caused ‘dog-ears’ that would necessitate a longer incision. The resultant scar is an S-shaped scar with a distal curve at the inferior border of the caput ulnae, extending in a radial and ulnar direction (Figure 1). At fourteen to twenty months follow-up of eleven patients undergoing bilateral surgery, the author found 60-75% reduction of excess skin (determined using the pinch test and verified with callipers), and in two patients the tightened skin also reduced venous prominence bilaterally.

Figure 1. The S-shaped incision line curves around the distal border of the caput ulnae, ending in a horizontal direction in the relaxed skin tension lines in the ulnar as well as radial direction. After Handle et al. 2011 [57].

A less invasive technique to address wrinkles and skin excess carried out by Aust [58] (LOE-4) used percutaneous collagen induction therapy. This treatment, also known as medical needling, is carried out by rolling a needling device (in this case an Environ Medical Roll) on the dorsum of the hand, creating thousands of closely neighbouring microwounds under regional anaesthesia. The resulting dermal inflammation triggers the release of growth factors including epidermal growth factor, fibroblast growth factor and transforming growth factor leading to improved collagen deposition – essentially an inflammatory response. The author reported improved skin texture, skin tightening, dermal neovascularisation and no change in pigmentation. However, no measurements of improvement were given.

b) Venous Prominence

Whilst marketing material aimed directly at patients refers to three modalities - sclerotherapy, endovenous laser therapy and phlebectomy - to rectify prominent hand veins, the latter does not appear to be the subject of any high quality peer-reviewed publication. One brief correspondence suggests it may be a useful treatment but the author notes it is technically demanding [25] (LOE-5). Of the remaining publications addressing venous prominence in the hand, those currently in print for sclerotherapy or endovenous laser therapy are of evidence level 4.

The main pieces of work on hand sclerotherapy are by Bowes & Goldman [21] (LOE-4) and Duffy [23] (LOE-4). Bowes described his experience of sclerotherapy in seven female patients (fourteen hands) using sodium tetradecyl sulfate sclerosant. Hand appearance was photographed preoperatively, postoperatively and at final follow-up an average of 3.2 years later. Efficacy was rated using a defined semi-quantitative score, according to which a 90-100% improvement was observed (that is, minimally apparent residual vessels or complete disappearance). The authors' reported '97.8% average improvement' has little meaning since mathematical transformations (such as mean averages) cannot validly be applied to semi-

quantitative scores, but the overall impression was that sclerotherapy achieved the task of obliterating the appearance of dorsal hand veins. No serious complications were observed, with mild swelling and erythema resolving quickly.

Duffy compared his retrospective eleven-year experience of hand sclerotherapy of 100 female patients, using either high or low concentrations of sclerosant (sodium tetradecyl sulfate or polidocanol in either group). One vein was spared (for future emergency venous access rather than for venous drainage) and treatment was repeated weekly if the response was inadequate.

High concentrations of either sclerosant were found to be more efficacious than low concentrations. In an earlier paper Duffy commented that smaller veins in younger patients can be more resistant [22] (LOE-5). Accordingly in this report the author recommended high concentrations in young patients but indicated that low concentrations may be adequate to treat the more fragile veins of elderly patients.

Postoperative thrombi were almost ubiquitous (occurring in 95% patients) and were treated by microthrombectomy. Additionally, 82% of patients developed mild upper limb oedema and 7.5% developed severe swelling. Half the patients experienced moderate discomfort (related to thrombi) and this was severe in a further twenty percent. A single patient developed paraesthesia in the distribution of the superficial branch of radial nerve, presumably resulting from trauma during attempted cannulation, and fourteen percent underwent some recurrence due to neovascularisation. The safety and long-term efficacy of this procedure has therefore not been adequately demonstrated.

Endovenous laser therapy was examined in a study of 54 hands in 28 patients [26] (LOE-4), although this was essentially a description of the author's experience without defined outcome measures. It was performed reportedly with no significant problems in an outpatient setting using tumescent anaesthesia, which provided anaesthesia, vasoconstriction, venous compression and a heat sink. Around two thirds of patients also received midazolam sedation.

The laser fibre was introduced to the veins via a sheath and an average of four veins treated per patient. The author used a 940nm diode laser and a 600µm fibre, delivering 7W power and pulling the fibre back through the vein at a rate of two millimetres per second. Total operative time was 45±20 minutes per hand. A compressive dressing was applied postoperatively. Eighteen of 28 patients received treatment to both hands simultaneously, the remainder undergoing either staged or unilateral therapy. The authors reported that patients tolerated the procedure well, with no specific comments regarding patients who had bilateral simultaneous procedures. Patients were told they could resume usual activities immediately if they had not received sedation or the following day if sedation had been administered.

After a mean of thirteen months follow-up, one postoperative complication was reported - a small skin burn at a laser exit site, left to heal conservatively. All patients experienced ecchymosis and hand swelling for around two weeks, and two patients required postoperative oral analgesia. All patients were reportedly satisfied with their results although no attempt was made to quantify this formally. Shamma considered this a superior technique to sclerotherapy, which in the upper limb required higher concentrations of sclerosant than in the leg and, as noted elsewhere, can result in a tender, phlebitic cord [26].

From the little evidence available, whilst efficacies of sclerotherapy and endovenous laser therapy appear similar, sclerotherapy appears to be associated with a higher incidence of significant complications such as severe postoperative pain and swelling. However, start-up costs for laser therapy may be prohibitive, and any modality aiming to ablate dorsal hand

veins (even if the practitioner seeks to preserve one) inevitably restricts future options for intravenous access.

c) Volume Replacement

Several volumetric hand rejuvenation procedures have been reported, but only one study has investigated their anatomical basis. Using histologic analysis and confirmed by duplex ultrasound scanning, Bidic [27] (LOE-4) described three distinct fatty areolar laminae and three fascial layers. The superficial lamina in more obese cadavers appeared to have more fat cells to obscure the appearance of veins, tendons and bones. Dorsal hand veins and sensory nerves were present in the intermediate lamina, and extensor tendons were found in the deep lamina. The author suggested that fat grafts or fillers injected into the superficial lamina could be carried out without jeopardizing the dorsal veins, sensory nerves or extensor tendons. Volar to dorsal adhesions from fascial sheaths surrounding perforating arteries and veins were identified using lead oxide injection [27] and could account for the lumpy compartmentalisation sometimes seen with injection of filler. The authors suggested aggressive massage to distribute injected filler evenly while preserving perforating vessels.

Volume-enhancing hand rejuvenation modalities are supported by the best (LOE-2) evidence available in this field, both using autologous fat [29,30] and non-autologous filler material [37]. Five further level 4 papers support the use of both autologous and non-autologous fillers for hand rejuvenation.

Autologous Fat Grafting

In 1985, Pierre Fournier presented a modified fat grafting technique which he called ‘microlipoinjection’, in which 13-gauge needles attached to ordinary syringes could be used to harvest fat for transplantation [59]. Grafting of fat took place by bolus injection and massage distribution.

This was followed some years later by Lauber, Abrams and William Coleman [36] (LOE-5), who harvested graft material using tumescent liposuction and reinjected it to the dorsum of the hand as a mound to be redistributed by massage. An assessment of graft longevity was not given.

Sydney Coleman has popularised ‘modern’ autologous fat grafting in all body locations, including in the dorsum of hand. Coleman (LOE-4) gives a clear description of the technique for autologous fat grafting [31], in which intact fat cells are harvested from donor sites tumesced with local anaesthetic and adrenaline, using a syringe and blunt cannula and avoiding excessive negative pressure (which could damage fat cells both mechanically and through lowering the boiling point of fat towards room temperature). Centrifugation of the harvested fatty material (3000 rpm for three minutes) yields a three-layer centrifugate. The uppermost oil from ruptured fat cells is decanted and wicked, the lowermost aqueous portion drained out, and the remaining middle portion consists of live, donor fat cells.

Currently the most accepted technique for injecting fat grafts aims to maximise contact between fat cells and recipient tissue. To achieve this, small aliquots or fat parcels are deposited in various directions and, if possible, planes. The alternative technique described earlier, of injecting a single dorsal fat lump and dispersing it by massage, would leave all but

a rim of outermost fat cells without the potential for revascularisation, potentially leading to poor graft survival, contour irregularities, fat necrosis and oil cysts. Coleman acknowledges that hand rejuvenation by fat grafting is not 'anatomical', in the sense that an attractive young hand is not fat, but instead fat is used to simulate thicker skin and subcutaneous tissue, soften the colour and definition of extensor tendons and veins, and support the skin [31].

Butterwick's studies on hand rejuvenation by fat grafting examine operative technique using a double-blind randomised controlled trial and side-by-side two-hand model. Low study numbers prevent these well-designed studies from attaining level 1 evidence. The first [29] (LOE-2) compared survival of centrifuged versus uncentrifuged fat grafts for dorsal hand augmentation, using aesthetics, venous prominence and depth of metacarpal space as surrogate markers. Fourteen patients were evaluated up to five months after injection of ten millilitres of centrifuged or non-centrifuged fat. Surprisingly there was a preference for the non-centrifuged side at one month follow-up, but this was replaced by a preference for centrifuged fat at three and five months in all patients.

Butterwick's second randomised controlled trial [30] (LOE-2) was a similar study in terms of design and outcome measures, this time comparing the survival of fresh or frozen fat grafts (fast frozen to -40°C , and slow thawed prior to use). Surgical technique was generally similar to that of Coleman [31]. Interestingly, at all time points there was a strong consistent aesthetic preference for frozen fat, and venous prominence and metacarpal space depth was also lower in that group. Whilst a physiological basis for improved survival of pre-frozen fat grafts is difficult to explain, this study indicates that frozen fat grafts appear to be at least as effective as fresh graft. This offers the potential for a single modest volume harvest followed by repeated small volume transfers of fresh followed by frozen fat.

Butterwick acknowledged that the follow-up interval was short in these studies. Moreover, the subject of investigation in the earlier trial - fat graft centrifugation - is less a matter of debate now than it was at the time, since either centrifugation or filtration of harvested fat has become accepted and standard practice as a means of improving survival of fat graft injectate. Regarding the second study, freezing of harvested fat in the United Kingdom would be governed by legislation proscribing the storage of human tissue [60], and in practice would be difficult to carry out. Therefore these high quality studies have little practical relevance to current practice, except perhaps to document that autologous fat grafting in general (irrespective of trial study group) appears an effective means of hand volume replacement.

Non-Autologous Fillers

Soft tissue augmentation of the dorsum of hands is probably carried out more commonly using non-autologous fillers than autologous fat (owing to the reduced cost and facility requirements of the former), although comparative data does not exist. Fillers described for this purpose in the literature include hyaluronic acid (HA), collagen, poly-L-lactic acid (PLLA), polymethylmethacrylate (PMMA) and calcium hydroxyapatite (CaHA), but few are the subjects of high level evidence studies.

Hyaluronic Acid and Collagen

However, one small but otherwise well-designed double-blind randomised controlled trial [37] (LOE-2) compared the use of 1.4ml HA (Restylane) and 2ml collagen (Cosmoplast) fillers for dorsal hand soft tissue augmentation in opposing hands of ten female patients.

Serial photographs obtained at one week and one, three and six months were scored by two blinded physicians for rhytid clearance, vein clearance, bony prominence and soft tissue atrophy. Additionally, patients scored each side for tolerability and satisfaction with the outcome.

Injections of HA filler were rated as significantly more painful, possibly because the collagen filler formulation included 0.3% lidocaine. There was a modest, non-significant, higher patient satisfaction following use of HA. However, physician evaluators rated HA as significantly superior to collagen using the indices of soft tissue augmentation at all time points. Side effects noted by the study were generally mild: pain, tingling and bruising following injection. One patient - in the collagen filler group - experienced nodule formation. Overall the authors favoured the use of HA over collagen filler.

Other evidence relating to these fillers is of lower level evidence. Hartmann [34] (LOE-5) reported the use of stabilised HA (Macrolane™ VRF290, Restylane Vital and Restylane Vital Light) in two patients. In one, Macrolane™ was injected subcutaneously in a fan-shaped pattern using a blunt 18-gauge cannula through a small incision made centrally in the proximal dorsum of the hand. In the other, Restylane Vital and Vital Light was injected more superficially (dermal to sub dermal level) with a 30-gauge needle using a tunnelling and tenting technique for fine correction or to correct less severe lipoatrophy. After injection, the material was massaged in. Both procedures were carried out under topical local anaesthesia and the patient treated with Macrolane™ received additional local anaesthetic injections at the incision site. Outcomes were clinician-recorded subjective observations, finding improved appearance with reduced visibility of veins and tendons and symmetrically filled interphalangeal spaces. No complications were reported, although as a two-patient study the power to detect complications would be very low.

A larger series of twelve patients treated with porcine collagen (Dermicol-P35 30G) for volume replacement in the hands (bilaterally) was published the same year [35] (LOE-5). Ten women and two men had the treatment carried out under topical anaesthesia using serial puncture or the linear threading technique, followed by firm massage to evenly distribute the filler. At 8-24 weeks, patients were 'very satisfied' with 23 out of 24 hands and 'satisfied' with one out of 24. Minimal to no swelling, mild discomfort lasting one to two days and minor bruising (two hands) were reported. At three months 22 out of 24 hands maintained cosmetic improvement. Comparison of the results of the two latter papers cannot be made as there were no standardised measurements of improvement. Both Hartmann and Inglefield reported good patient tolerance to the treatments, with early return to normal activities.

Poly-L-Lactic Acid

The use of PLLA as a semipermanent dorsal hand filler receives sparse attention in the literature. Whilst none of the three existing publications provide sufficiently high quality evidence to either promote or refute this indication, the reports are generally not encouraging. In a retrospective review of its use in 26 patients, Sadick [40] (LOE-4) described high patient satisfaction in "the majority of patients", although this was not quantified and no formal outcomes were defined. 'Few adverse events' took place according to the authors, but this corresponded to a reported 11.4% complication rate after excluding pain and swelling.

Redaelli [39] (LOE-4) retrospectively reported the outcome of injecting PLLA filler in 27 patients using a satisfaction scoring system (based on patient satisfaction score, physician's satisfaction score and photograph score) taken before the first treatment and after the last

treatment given. Scores of one to ten were given by the patient, physician and for the pictures (although the basis for this scoring was not given) and the average of these termed the 'definitive graduated score' (DGS). The mean DGS was 6.55, with 22.2% of patients having unsatisfactory results (of less than five). The authors explained that most of these patients had been treated early in the series using too dilute solutions. Since then, a protocol had been set up comprising:

First session: 2ml for hands using a 5ml dilution (with 0.5ml 3% carbocain and water) of polylactic acid bottles.

Subsequent sessions: 1.5-2ml per hand using a 6-8ml dilution of polylactic acid bottles.

There were reportedly "no important side effects". However, soft tissue irregularity was suggested in one patient ('small nodulation unnoticed by the patient').

The most recent report of the use of PLLA for hand rejuvenation in a single patient (Randon 2010, LOE-5) recounts the author's experience but otherwise adds little more to the evidence. Thus the literature is weak in this area, but hints at a treatment that commonly requires multiple treatments, is frequently uncomfortable and sometimes has little perceptible benefit.

Calcium Hydroxyapatite

Radiesse was approved for the treatment of severe lines and wrinkles of the face in 2006³². In 2007, Busso and Applebaum (LOE-5) reported their use of this CaHA filler (with the addition of lidocaine) for hand recontouring [28].

Edelson [32] (LOE-5) recommended mixing Radiesse (1.3ml in Luer-Lok syringe) with 0.5mls of 2% plain lidocaine (in 3ml Luer-Lok syringe) using a Luer-Lok to Luer-Lok connector prior to injection, reducing its viscosity and extrusion force. In his description of technique and experience, the author presented pre- and posttreatment (up to 28 weeks) images of two patients, with the effects of rejuvenation still evident at 28 weeks. Adverse effects other than transient hand swelling were considered infrequent, although no objective comment could be made from this very limited series.

In a short communication, Gargas [33] (LOE-5) described their technique of subcutaneously injecting Radiesse into the dorsal hands of their patients using a similar technique of bolus and massage dispersal, except under field infiltration local anaesthetic (0.5ml of lidocaine). The author recommended limiting injections to one or two to decrease the chance of irritation to subcutaneous tissue. Patients were allowed to return to normal activities as soon as they felt comfortable. Similar to Edelson, reported adverse effects were limited to local mild swelling and bruising which resolved in one to two weeks [33]. Patients were reviewed two weeks after treatment for more volume injection if required. No objective results of their treatment were reported.

Sadick [41] (LOE-4) used topical anaesthesia prior to injecting CaHA into the dorsum of hands by retrograde delivery. In their case series of ten patients assessing the safety and efficacy of this hand rejuvenation technique, patients, principle investigator and an independent evaluator evaluated wrinkle severity and improvement. The effects of treatment were still present at twelve months, with sixty percent of patients giving satisfactory ratings at this period, with improvement in dorsal hand wrinkles.

d) Skin Changes

Multiple modalities aimed at rejuvenating skin have been described, but relatively few of these have been given specific attention in the literature for rejuvenating the skin of the hand. Dorsal hand skin differs from that of the face, for example, in having thinner dermis, an inferior blood supply and fewer appendages [48]. Descriptions of skin rejuvenation at other sites may therefore not be safely extrapolated to the hands.

The only reasonably high evidence level papers published for rejuvenation of dorsal hand skin relate to fractional photothermolysis [44] (LOE-2) and Plasma Skin Resurfacing (PSR) [42] (LOE-2). Other modalities have been considered at lower evidence level, including the Erbium:YAG laser [14,45] (both LOE-4), salicylic acid peel [17,48] (both LOE-4) and IPL [43] (LOE-4).

Fractional photothermolysis uses a mid-infrared laser to produce discrete thermal injuries, termed microscopic treatment zones (MTZs) surrounded by spared areas from which regeneration takes place. Jih [44] (LOE-2) carried out a prospective randomised study comparing fractional photothermolysis with no treatment in the randomised hands of ten patients (who underwent symmetrisation after the study). Patients with Fitzpatrick skin type V or above were excluded. On the treated side, five treatments were carried out at two to three week intervals using a 1550nm diode-pumped erbium fibre laser, providing 8-9mJ/MTZ and a treatment density of 2500MTZ/cm² achieved with ten passes, under topical anaesthesia.

Photographs and skin biopsies were obtained before treatment and one & three months afterwards. Photographs were assessed subjectively by investigator and patient for skin roughness, wrinkling and pigmentation; biopsies were examined histologically. Photographs showed improvement in skin roughness, skin wrinkling & pigmentation at one & three month time points (although physician assessors felt there to be some loss of improvement in pigmentation by three months points), and biopsies demonstrated thickening of epidermis and increased dermal collagen density, as would be expected in response to injury. All patients tolerated the procedure and rated pain as mild to moderate. Unwanted effects appeared limited to transient erythema and swelling.

Plasma skin resurfacing (PSR) uses ultrahigh energy radiofrequency to convert nitrogen to plasma, which is directed to skin via a handpiece, transferring heat and producing its clinical effect. Alster [42] (LOE-2) investigated ten patients undergoing PSR to the hands, neck or chest under topical anaesthesia. Energies were set at 1.0, 1.5 or 1.8J with 10-20% pulse overlap, 1-4Hz pulse repetition and a single pass. Standardised photos obtained before treatment and at days four, seven, fourteen, thirty and ninety were used by independent medical assessors to evaluate texture, pigmentation and wrinkle severity according to a standardised grading scale, and blinded histological comparison was also made of punch biopsies taken before and ninety days after treatment.

Following PSR there was 48% mean improvement in rating scale measurements in treated hands. Statistically significant reductions were seen in wrinkle severity (4.1 to 2.4) and hyperpigmentation (1.8 to 0.4), both at ninety days. Histologically all specimens exhibited epidermal thickening, decreased solar elastosis and increased dermal collagen deposition. All patients experienced erythema, swelling and desquamation in response to PSR, but there was no infection, unwanted scarring or hypopigmentation. The authors felt that higher energy settings produced greater clinical benefit, although the size of the study precluded meaningful subgroup analysis so this was a clinical impression. The disadvantage

of higher energy settings was felt to be prolonged healing time (fourteen versus seven days), and the recommendation given was for more treatment sessions of lower energy.

The Er:YAG laser is marketed as safe for resurfacing photo damaged hand skin, prompting Jimenez [45] (LOE-4) to investigate its use in seven patients. A five millimetre spot size at one joule ($5\text{J}/\text{cm}^2$) energy over two to three passes resulted in mostly 'poor' cosmetic improvement at follow up six months later. Two patients developed bacterial infections during healing, and healing was alarmingly prolonged (two to three weeks), exceeding what would be expected in the face using similar treatment parameters. The latter suggests that poor efficacy did not result from undertreatment (in terms of energy delivery). Despite this the authors concluded that Er:YAG laser resurfacing could safely be performed in the hands, apparently disregarding their 29% significant wound infection rate or the fact that 43% of patients said they would not have the treatment again or recommend it to others.

The only other study involving Er:YAG treatment to the hands [46] (LOE-4) adds little additional information. This is a seemingly larger prospective study of 21 patients, although only three of those received laser treatment to the hands (the others receiving it to the face or neck). Inclusion criteria were relatively minor skin changes - superficial fine lines with fine surface textural or pigmentary changes, and at $2.5\text{J}/\text{cm}^2$ the energy density was half that in Jimenez's study. It is unclear how the authors rated photographs obtained at various time points, up to two months post procedure - their methodology states only that "*blinded objective grading of photographs was performed by four aesthetic surgeons using matched and morphed two month postoperative digital images.*" Thus the outcome, that there was 48% improvement in the appearance of the dorsal hands, is difficult to interpret. Unwanted outcomes again included erythema and swelling, along with crusting, pain and one Staphylococcal infection. Complications were not subdivided by anatomical site of laser delivery so it is not known which of these related specifically to the dorsal hands.

Salicylic acid peels for rejuvenation of dorsal hand skin has been the subject of two publications, but we could not find strong evidence supporting its use. One paper could not be obtained¹⁷ but reference to it elsewhere [61] indicates that the author presented experience of fifty percent salicylic acid ointment in 81 patients to treat freckling, pigmentation and ageing changes of hands and arms, with apparently excellent results reported. No further information about methodology or results analysis is known.

Swinehart [48] (LOE-4) presented an uncontrolled retrospective review of experience of pretreatment combined with 50% salicylic acid peel to the dorsum of the hands in eleven patients. 0.1% tretinoin was used to inhibit melanogenesis and loosen epidermal attachments, thought to enhance subsequent penetration of peel. 20% tricarboxylic acid (TCA) was used to pretreat actinic keratoses, seborrhoeic keratoses or lentigines. During the peel itself, salicylic acid paste was applied and the treated area dressed with cling film and Kerlix. Dressings were changed at 48 hours and as required thereafter. Desquamation was usually complete by day ten and erythema subsided over three to four weeks.

The follow-up period or quantification method, if any, was not stated in this paper, and there was no control group. Nonetheless the author stated that all patients "experienced excellent results", there being "effective removal of ninety percent or more of cutaneous lesions." Without more methodological detail it is difficult to substantiate those views. Side effects included a burning sensation lasting two days and salicylism resulting from excessive systemic absorption, resulting in tinnitus or muffled hearing, which was self-limiting.

Goldman [43] (LOE-4) presented the use of intense pulsed light (IPL) to rejuvenate aged hand skin in 23 patients of Fitzpatrick skin types I and II presenting with solar lentigines and 'poor skin texture' (presumably rhytids). Four IPL sessions were performed at three to four week intervals using a 550nm filter, 6-9J/cm² fluence, 15-20ms delay and pulse duration of 4.2-4.5ms. No topical anaesthesia was necessary, patients receiving only cold dressings before and after treatment. Semi-quantitative assessment of colour, extent and density of solar lentigines was then carried out by the physician four weeks after the procedure. Patients also rated their satisfaction with the outcome.

Despite poor skin texture being an inclusion criterion for the study, no assessment of outcome with regards skin texture was made. Outcome assessment was subjective and there was no control group. The authors' conclusions, that there was improvement in lesion clearance and skin texture with high patient satisfaction, therefore cannot be substantiated. More patients than physicians rated their outcome as 'satisfactory' (rather than 'excellent' or 'good'), indicating they were less impressed with the results. The published case photographs appear to show fading of solar lentigines but the hands nonetheless appeared to retain an aged appearance after IPL treatment.

Hexsel and colleagues⁶² (LOE-4) carried out a comparative study between cryotherapy and dermabrasion for the treatment of solar lentigo of the back of the hands. A total of ten patients were treated with cryotherapy in their left hand and dermabrasion in the right hand without anaesthesia. The authors found that stinging during the procedure was more intense with cryotherapy. Three months post procedure, hyperpigmentation was more common in the hands treated with dermabrasion and hypopigmentation more common in the hands treated with cryotherapy. At six months, the treatment modalities exhibited similar rates of hyperpigmentation but hypopigmentation remained more common in the cryotherapy treated hands (55.55% vs. 11.11%). Recurrence rate at nine months was similar between both treatments at 55.55%.

e) Combination Therapies

Several authors have discussed the need for combination therapy to address the different components of ageing that take place in the hand. Almost all have considered the need for fat grafting (addressing volume, skin laxity and visible veins and tendons) in addition to other treatments, such as rhytidoplasty [49] (LOE-4), tricarboxylic acid (TCA) chemical peel [53] (LOE-5), laser therapy [6] (LOE-5) and dermabrasion [54] (LOE-5). Several reviewers have also summarised the multimodal therapies available for hand rejuvenation [50-52,55].

Aboutidib Júnior considered fat grafting the most effective modality for hand rejuvenation, although his technique differed somewhat from that popularised by Coleman - in using high pressure suction for fat graft harvest, washing harvested fat in saline rather than centrifuging, and distributing injected fat by massage rather than deposition of multiple small parcels. His case series [49] (LOE-4) presented experience of combining fat grafting with rhytidoplasty (presumably of the hands, although this was not actually explicitly stated) in 47/72 patients, the remainder having fat grafting alone. However some methodological vagueness limits the usefulness of that series as evidence. Outcome quantification was not described so the very precisely attributed patient satisfaction of 98.6% is difficult to corroborate or comprehend. Other measures were imprecise (e.g. that oedema lasted '*about thirty days*' postoperatively),

subjective (e.g. that there was moderate tissue absorption at one year '*without involving the cosmetic result*') or prone to recall bias (e.g. that '*no complaints of pain were recorded*').

From our contemporary understanding of fat grafting we would anticipate poorer survival and higher rates of resorption, fat necrosis and lipid cyst formation from the technique described. Fournier, who uses a similar method of fat grafting by bolus injection and massage distribution, has recently described his experience and long-term outcomes, estimating that approximately 10% patients develop dorsal hand fat cysts, that 25-50% of injected fat is viable, and that some patients exhibit total graft resorption.

The few reviews of hand rejuvenation outline a number of therapeutic options for hand rejuvenation, including topical retinoids, alpha-hydroxy acids, bleaching agents, microdermabrasion, chemical peels, cryotherapy, IPL, laser, photodynamic therapy, autologous and non-autologous fillers and combination therapies. However little data is presented in these reviews and most of the citations do not provide evidence specific to hand rejuvenation [51,52,63].

CONCLUSION

Surgery for hand rejuvenation is controversial. Medical students are taught that there is no such thing as aesthetic hand surgery – function is paramount. For a growing number of practitioners and patients this no longer appears to be the case. Irrespective of their ranking as (only) the second most aesthetically important body part, however, the prime contribution of hands to daily life is unquestionably functional. In this context it is difficult to justify any risk to personal livelihood, self-care and the pursuit of normal life that could result from hand surgery performed for non-functional reasons. As such, an acceptable rejuvenation modality must exhibit an exemplary risk profile. A significant proportion of plastic surgeons would probably consider no degree of adverse risk acceptable for the purpose of hand rejuvenation.

Despite this, hand rejuvenation is requested by patients and offered by practitioners, and as modalities for rejuvenating the rest of the body become more sophisticated, the disparity between senescent hands and a youthful face will increase. Thus we anticipate the demand for hand rejuvenation to continue and expand. Objective assessment of the safety and efficacy of these procedures may take on increasing importance in years to come.

Practitioners wishing to carry out evidence-based hand rejuvenation face several challenges. In general there is a paucity of clinical evidence and practically no such evidence of very high quality. Many reports are anecdotal, based on surgeons' experience or preference, or applied to the hands from rejuvenation procedures used in other anatomical sites without specific evidence. Quantification of outcomes is carried out inconsistently or not at all, and series are generally too small to preclude meaningful statistical analysis. With the current state of the literature it is not possible to provide definitive evidence-based guidance on hand rejuvenation.

Despite this, some trends can cautiously be discerned from an overall view of the literature. Firstly, it appears that ageing of the hands follows several distinct processes - venous prominence, skin excess, skin photo-ageing and volume loss - which may occur to a greater or lesser degree in different individuals. Of these, venous prominence is the single change found, in one study, to confer the greatest appearance of ageing.

Ageing changes can be addressed individually or using combination modalities to tackle several sequelae at once. Some individual modalities address more than one sign of hand ageing - for instance, treatments correcting volume loss also reduce venous prominence.

Skin excess has been addressed by open excision, either through a dorsal wrist crease scar [2,4] or an ulnar scar [3,57] or percutaneous needle collagen induction therapy [4,58]. On empiric grounds the excisional techniques would be expected to have a higher risk profile than percutaneous needle therapy - particularly in terms of nerve injury, swelling, haematoma and stiffness. Thus one should actively seek evidence that decisively refutes the suspicion of harm resulting from these excisional treatments. In the absence of such robust safety data, they are not currently recommended. There is insufficient data for any of these modalities to conclude on either their safety or efficacy.

Venous prominence has been treated by sclerotherapy, endovenous laser therapy and phlebectomy, although the latter is almost completely unreferenced in the medical literature. The largest series of sclerotherapy to the hands showed higher concentrations of sodium tetradecyl sulfate or polidocanol sclerosant to be more efficacious than lower concentrations [5-7,23]. However, microthrombi (treated by thrombectomy) were almost universal and upper limb oedema very common, being severe in 7.5% cases. Half the patients experienced moderate and twenty percent experienced severe discomfort; one patient experienced superficial branch of radial nerve distribution paraesthesia and fourteen percent had recurrence due to neovascularisation. On the basis of admittedly weak evidence, the safety and long-term efficacy of this technique is dubious. It should therefore be approached cautiously and outcomes carefully scrutinised. Similar precautions should be applied to the use of endovenous laser therapy, the efficacy of which has not been quantified formally - a retrospective review of experience in 54 hands reported only that all patients were 'satisfied'. In this series complications were relatively minor, the most severe being one exit wound burn, which healed conservatively. One cannot accurately determine safety and efficacy based on this study. At very least, these destructive techniques necessarily reduce future options for intravenous access, which may be relevant to the administration of medical treatment (including anaesthesia) to a population who, by self-selection, one must presume are entering a stage of life in which medical comorbidity becomes more common.

Hand rejuvenation by volume enhancement – both autologous [8,29,30] and non-autologous [37] - is supported by the best level evidence in this field. Butterwick carried out double-blind randomised controlled trials to investigate, separately, survival of centrifuged versus uncentrifuged fat grafts, and survival of fresh or frozen fat grafts. Thorough outcome quantification included aesthetics, vein prominence and depth of metacarpal space. More important than the outcomes of the study comparisons (favouring centrifuged fat at the longest follow-up points, and favouring frozen fat at all time points) these studies show that autologous fat grafting as performed using Butterwick's documented method survives for at least five months, and that volume replacement and aesthetic improvement both occur as a result. The author herself acknowledges that the follow-up period was too short to assess long-term survival, and patient numbers were relatively small. The best available study of non-autologous fillers for hand rejuvenation [37] slightly favoured HA over collagen. This study was also limited by study size and short follow-up.

The best available evidence for rejuvenation of dorsal hand skin relates to fractional photothermolysis [44] and PSR [42]. Photographs and skin biopsies one & three months after fractional photothermolysis showed improvement in skin roughness, skin wrinkling &

pigmentation. However, there was a loss in physician-rated improvement in pigmentation by three months, and no further time points were sampled, reminding the reader of the possibility of a transient response. PSR resulted in improved wrinkle severity and hyperpigmentation associated with epidermal thickening, decreased solar elastosis and increased dermal collagen without major adverse events, in a small series of ten patients. The longevity of the treatment is not known, and larger supportive studies do not exist.

Whilst there exists no high level evidence regarding the Er:YAG laser for rejuvenation of dorsal hand skin, the experience of Jimenez [45] (LOE-4) appears not to support its use both on grounds of safety and efficacy. Cosmetic improvement was rated as 'poor' in six of seven patients at six months, noting (despite the small series) cases of bacterial infection and prolonged healing. At best one could state that there exists no high level definitive evidence, and patients should be counselled accordingly.

Chapter 43

BODY DYSMORPHIC DISORDER

Valerie Picavet and Peter Hellings*

University Hospitals Leuven, Belgium

KEY POINTS

- Body dysmorphic disorder represents a new name for an old syndrome [1]. Its recognition is critical since an unrecognised preoperative BDD patient may become a severely, and sometimes dangerously, dissatisfied postoperative patient. All plastic surgeons should know about BDD [1-4].
- The psychological impact of nasal deformities and its surgical correction cannot be underestimated [5] and cosmetic rhinoplasty is suspected of being the most frequently requested and performed surgical procedure in this population [6,7]. Unsatisfied patients despite a good cosmetic rhinoplasty result have been reported for as long as the procedure itself [5,8,9]. This chapter aims to explore BDD in general, as well as addressing the particular concerns of BDD in the rhinoplasty population.

HISTORY AND DEFINITION

In 1886, Morselli introduced the term “dysmorphophobia” in the European medical literature [10]. Etymologically this term derives from the Greek “dysmorphia” meaning ugliness, specifically of the face and “phobos” meaning fear. Dysmorphia first appeared in “the histories of Herodotus”, referring to the myth of the ugliest girl in Sparta [11]. In the medical literature dysmorphophobia has mostly been defined as the subjective feeling of ugliness or physical defect despite a normal appearance [10,12]. Since the introduction of dysmorphophobia, similar symptoms have been categorised under a variety of names. In the beginning of the twentieth century Janet reported cases of l’obsession de la honte du corps (obsession with shame of the body) and classified it within a large class of syndromes similar to obsessive-compulsive disorder [13]. Similar, Kraepelin described a dysmorphophobic

* Corresponding Author’s Email: Peter.Hellings@med.kuleuven.be.

syndrome and urged it to be classified as a compulsive neurosis [14]. One of psychiatry's most famous patients, Freud's Wolf-Man with "hypochondrial paranoia", represents a classic case of dysmorphophobia in the psychoanalytic literature. This patient was convinced he was victim of a nasal injury caused by dermatological treatment of obstructive sebaceous glands, ruining its nasal contour. Brunswick, the Wolf Man's second psychoanalyst, wrote "he neglected his daily life and work because he was engrossed to the exclusion of all else, in the state of his nose" and "his life was centred on the little mirror in his pocket and his fate depended on what it revealed or was about to reveal" [15]. In the 1930s "beauty hypochondria" (*Schönheitshypochondrie*) and "one who is worried about being ugly" (*Hässlichkeitskummer*) are other colourful labels to describe BDD-like preoccupations with imagined defects in appearance [16].

Whereas dysmorphophobia has a clear presence in the European literature, the disorder was only rarely mentioned in the American literature [1]. Moreover, cases of this disorder may first have appeared in the cosmetic and dermatology literature, describing the "minimal deformity" and "insatiable" patient [17,18]. Only in 1980, dysmorphophobia entered the U.S. psychiatric nosology in the Diagnostic and Statistical Manual of Mental Disorders- third edition (DSM-III). It was categorised as an example of an atypical somatoform disorder [19]. With the publication of the DSM-III-revised in 1987, dysmorphophobia achieved diagnostic status and was officially termed "body dysmorphic disorder" [20]. Currently, BDD is categorised as a somatoform disorder [21]. This classification has been criticised, however, asserting that it should be considered as an obsessive-compulsive spectrum disorder or an affective spectrum disorder [22].

The present definition of BDD in the DSM-IV-Text-Revision requires three diagnostic criteria: (A) a preoccupation with an imagined defect in appearance (or if a slight defect is present, the persons' concern is excessive); (B) the preoccupation causes significant distress or impairment in one or more important areas of functioning and (C) the preoccupation is not better accounted for by another psychiatric disorder [21].

CLINICAL FEATURES

Preoccupations with Appearance

The hallmark characteristic of BDD is a preoccupation with some aspect of the appearance. BDD patients are convinced that some aspect of their appearance is unattractive or deformed. In reality, the area of concern appears normal or the flaw is minimal. Any part of the body may be the focus of concern. However the most common areas involved are the hair, skin and face, in particularly the nose [16,23,24]. The complaint about the appearance can be specific or vague and most BDD patients are concerned with more than one body part. Moreover, concerns might shift to another feature over time [16]. The preoccupations with appearance are difficult to resist or control, and on average consume three to eight hours a day [25]. They are often associated with fears of rejection and feelings of low self-esteem, shame, embarrassment, unworthiness, and being unlovable [25].

Intrusive Thoughts

BDD patients typically experience uncontrollable, intrusive thoughts about their appearance. They describe being unable to stop thinking about the perceived defect, some to the extent that they are able to focus on little else. These thoughts may increase in situations in which the person expects to be scrutinized [23]. Many BDD patients are unable to recognise that their concerns are excessive and nearly half of patients are delusional (i.e., certain that their view of the 'defect' is accurate) [25,26]. In addition, most BDD sufferers have delusions of reference, thinking that others take special notice of the 'defect', perhaps staring at it, talking about it, or mocking it [25].

Compulsive Behaviors

In an attempt to calm anxieties concerning appearance, or to avoid the feared ridicule or rejection of others, BDD patients frequently engage in time-consuming repetitive and compulsive behaviours. Common behaviours include comparing with others, mirror checking, excessive grooming, camouflaging and excessive reassurance seeking about their appearance [16,22,23]. For example, Phillips and Diaz found in their evaluation of 188 subjects with BDD that 87% reported excessively checking their appearance in mirrors and other reflective surfaces; 88% also reported camouflaging behaviours such as using a hat or one's hand to hide the perceived facial defect [27]. Moreover, BDD sufferers frequently avoid situations and clothing that might expose their defect, such as examining oneself in mirrors, swimming or dating [16]. Compulsive behaviours are thought to contribute to the maintenance of BDD, as they prevent sufferers from habituating to the sight of their appearance and keep attention focused on the feature of concern [28]. However, many BDD patients feel that they cannot resist engaging in some of these behaviours, even when the behaviours themselves may worsen the defect, for example in skin picking.

Impairment in Functioning

Intrusive thoughts and compulsive behaviours may consume several hours each day and may lead to significant impairment in social and or occupational life [16,22,23]. 98% out of 188 BDD patients reported interference with their social and occupational life, and approximately thirty percent reported becoming housebound as a result of their condition [27]. Similarly, Phillips and colleagues reported in their study of 200 BDD patients that in the previous month, 36% (n=63) had been absent from work, and 32% (n=56) had skipped school because of the disorder [29]. Moreover, they reported that eleven percent had permanently left school [29].

Reduced Quality of Life and Emotional Distress

Quality of life in BDD patients is low. Phillips investigated the quality of life in 176 BDD sufferers using the Medical Outcomes Study 36-item Short-Form health Survey (SF-36) [30]. BDD patients scored markedly lower in all areas of mental health related quality of life compared to the U.S. normal and compared to patients with type II diabetes, with a recent myocardial infarct and with depression [30]. Moreover, more severe BDD symptoms were significantly correlated with poorer functioning and quality of life [30]. The emotional distress in BDD sufferers ranges from mild distress to severe and disabling emotional pain, leading to suicidal ideation and attempts [16,23,24,31]. Available evidence indicates that approximately 80% of individuals with BDD experience lifetime suicidal ideation and 24% to 28% have attempted suicide [32]. In addition, people with BDD have higher levels of hostility compared to healthy controls [16]. Anger has many sources: frustration over looking abnormal, not being able to improve one's appearance, lack of control, and feelings of being rejected by others or that others are mocking the defect [16]. Not infrequently, anger and violence are directed toward the surgeon or dermatologist who provided unsatisfying treatment [16]. Several cases of BDD patients who threatened, stalked, attempted to kill, or actually killed their dermatologist or plastic surgeon have been reported [9,16]. Finally, for some patients, the emotional desperation to improve the perceived defect can lead to self-harm. For example, the use of abrasive chemicals or razor blades to correct blemishes of the skin is not uncommon [33]. Moreover, some patients even perform their own surgery [7]. Veale described nine patients that performed "Do It Yourself" procedures in an attempt to alter their appearance [7]. This was either in desperation after being declined or unable to afford cosmetic surgery. For example, he reported a female patient, preoccupied by the ugliness of multiple areas of her body, who desired liposuction but could not afford it. Subsequently, she used a knife to cut her thighs in order to squeeze out the fat [7]. Similarly, Phillips described a patient who attempted to perform a rhinoplasty, by opening the nose with a razor blade and replacing the nasal cartilage with chicken cartilage in the desired shape [16].

Co-Morbid Psychopathology

Co-morbid psychopathology occurs frequently in BDD patients. Most common co-occurring disorders are (major) depression, social phobia, substance abuse, obsessive-compulsive disorder and personality disorders [25,27,33]. Depression has the highest rate of co-occurrence, with a lifetime rate of eighty percent and a current rate of 60% [34]. The onset of depression in patients with BDD tends to be either concurrent with or subsequent to the onset of BDD [29].

PREVALENCE AND DEMOGRAPHIC FEATURES OF BDD

Body dysmorphic disorder is not considered rare. The prevalence of BDD in the general community has been reported as 0.7-3%, with a higher prevalence in adolescents and young adults [35-38]. These prevalence rates may be underestimates as BDD is often present in a

hidden state [16,23,35]. BDD patients are embarrassed and reluctant to discuss their concerns. Veale and colleagues reported that 38% of their sample (of fifty patients) would not disclose their concerns to their general practitioners for fear of embarrassment, being misunderstood or not taken seriously [36]. Of the remaining 68% who did mention their concerns to their general practitioner, 83% were dissatisfied with the response [36]. Moreover co-morbid psychopathology might explain to a certain extent the under-recognition of BDD, even in a psychiatric setting. Finally, patients frequently show impaired judgment regarding the psychiatric origin of their concerns and often seek cosmetic treatment because they are convinced they warrant medical, rather than psychiatric attention [16,23]. Therefore, the prevalence of BDD in a cosmetic setting is suspected to be much higher with rates of 6-54% being reported [37-39].

The mean age of onset of BDD is late adolescence, however, BDD is usually diagnosed years later [16]. Although the gender ratio has varied in some clinical samples, BDD appears to affect men and women equally [21,27]. Information on ethnicity and BDD symptoms is rare. It has been shown that Afro-Americans of both genders are less dissatisfied with their bodies than Caucasians, Asians, and Hispanics, suggesting that ethnic background contributes to a person's vulnerability and risk for BDD [40]. However, BDD has been reported in numerous countries and continents around the world [25]. These case reports and series suggest that BDD's clinical features are generally similar across cultures, but that culture may produce nuances and accents [25].

COSMETIC TREATMENT IN BDD PATIENTS

For patients with BDD the treatment of choice is psychiatric pharmacological and/or cognitive-behavioural therapy [16]. The primary treatment for BDD does not consist of surgery. Nevertheless the literature reports that 50-76% of BDD patients sought and up to 66% received cosmetic treatment [2,6,41]. Patients refused by a cosmetic surgeon often engage in "doctor-shopping" until they find a provider who is willing to perform the desired treatment [16]. Therefore it has been suspected that the prevalence rate of BDD in a cosmetic setting is much higher than in the general population. In cosmetic settings rates ranging from six to fifteen percent have been reported [35,37,38], with some smaller studies mentioning rates as high as 54% [39,41]. The wide variety in reported prevalence is due to the application of different diagnostic tools and defect severity rating scales. It reflects the lack of a standardised approach for proper identification of BDD patients in this particular setting. Moreover, it raises questions regarding the utility of the present definition of BDD in a cosmetic surgery setting [42,43]. The first criterion of BDD refers to a preoccupation with "an imagined or slight defect in physical appearance". Cosmetic surgery patients often present with relatively slight defects in appearance, presumably consistent with the diagnosis of BDD. Such minimal flaws in appearance, however, are frequently judged as observable and correctable by the plastic surgeon, falsely excluding patients to meet the diagnostic criteria of BDD. In addition, in cosmetic patients dissatisfaction with an aspect of appearance serves as a motivational component for pursuit of cosmetic surgery [4,44]. Judgment of degree of dissatisfaction and preoccupation is therefore highly subjective [42,43]. Similarly assessing the resulting disruption in daily functioning as defined in the second criterion of BDD-

diagnosis is not straightforward [43]. Nevertheless, it has been suggested that the degree of emotional distress and behavioural impairment are more accurate indicators of BDD in a cosmetic surgery population than the size or nature of the physical defect [41,43].

BDD is reported in a wide variety of cosmetic procedures, but dermatological and facial plastic procedures seem to be most frequently sought by BDD patients [10,32,45], of which rhinoplasty appears to be the most commonly sought facial plastic procedure [6,7].

There is a general consensus that BDD should be considered a contraindication to cosmetic treatments [6,24,46,47]. Clinical reports and retrospective studies reveal that the vast majority of patients with BDD do not benefit from cosmetic surgery. After surgery, they show a low degree of satisfaction, a deterioration of BDD symptoms and may even become violent towards themselves and/or their surgeon [24,26,46]. Unfortunately, only very few prospective studies investigating the impact of BDD on satisfaction after cosmetic surgery are available [41,48,49]. Tignol et al. evaluated the effect of cosmetic surgery in 24 patients with a minimal defect in appearance, with (n=10) and without (n=14) BDD, five years after their request for cosmetic surgery [48]. Seven out of ten BDD patients had undergone cosmetic treatment, confirming that the majority of BDD patients receive cosmetic treatment. BDD patients were significantly younger at the time of cosmetic surgery compared to non-BDD subjects. Surprisingly, patient satisfaction with the intervention was high in both groups. However, six of the seven BDD operated patients still had a BDD diagnosis and exhibited higher levels of disability and psychiatric comorbidity compared to their non-BDD counterparts [48]. Similarly, Veale et al. found in their study of 29 patients seeking cosmetic rhinoplasty, that “possible BDD” patients (n=6) were no less satisfied with the outcome after rhinoplasty at either three or nine months compared to “non-BDD patients” [41]. The authors presumed that they might have identified a group of patients with subclinical or very mild BDD who are satisfied with cosmetic surgery. The weak methodologies of these studies make it difficult to draw firm conclusions. However, patient’s declared satisfaction with cosmetic treatment may explain to a certain extent why some plastic surgeons are convinced that BDD should not always be considered as a contraindication for aesthetic surgery [9,48]. On the other hand, a survey conducted among members of the American Society for Aesthetic Plastic Surgery (ASAPS) conducted in 2001 brought to light that 29% of aesthetic surgeons had been threatened legally and 2% physically by a patient with BDD [9]. Furthermore, cases of BDD patients suing their cosmetic surgeon for operating on them, instead of recognizing BDD, have been reported. These cases bring to light additional concerns associated with treating BDD patients and highlight the importance of proper identification of BDD patients in this particular setting.

RHINOPLASTY AND BDD

The central role of the nose in the face makes the nose one of the most common areas of concern in patients with BDD [16,23,26]. As a result, cosmetic rhinoplasty is suspected to be one of the most frequently requested and performed surgical procedures in this population [6,7]. In a study of 200 patients with BDD, Crerand et al. found that rhinoplasty was the most frequent sought (n=33 patients) and performed (n=23) cosmetic surgical procedure [6]. Similarly, Veal et al. found in their analysis of 25 BDD patients with a history of aesthetic

surgery that seventeen underwent cosmetic rhinoplasty [7]. Moreover, in this retrospective study rhinoplasty had the highest level of dissatisfaction after cosmetic surgery [7]. Interestingly, previous research with rhinoplasty patients has found no correlation between the perceived degree of nasal deformity and the amount of psychological disturbance [41,50]. These findings suggest that in this population, the amount of distress and psychological functional impairment may be better indicators of BDD than the degree of nose imperfection [43,50].

To our knowledge there are only three prospective studies investigating BDD in a cosmetic rhinoplasty setting [41,49,50]. Veale and colleagues investigated the prevalence of BDD in 29 patients seeking cosmetic rhinoplasty and evaluated its impact on surgery [41]. In the first stage of the study they found that six patients (21%) had a possible diagnosis of BDD based on a screening questionnaire [41]. This screening tool, the Body Dysmorphic Disorder Questionnaire (BDDQ), had however not yet been validated in a cosmetic surgery population. There were neither significant differences on the depression or anxiety scores, nor on the rating of the nose imperfection in “possible BDD” patients and “no BDD” patients. Furthermore, “possible BDD” patients were no less satisfied with the postoperative result three and nine months after surgery [41]. As mentioned previously, the authors presumed that they might have identified a group of patients with subclinical or very mild BDD who are satisfied with cosmetic surgery. The authors subsequently compared the patients without BDD undergoing rhinoplasty and BDD patients with nasal preoccupations seen in a psychiatric setting. They found that the latter were younger, more depressed, more anxious and more preoccupied with their nose [41]. Moreover they were significantly less functional at work, in their social life and in relations. Finally BDD patients were more convinced that their life would dramatically change after rhinoplasty [41]. The small scale of this study, however, questions its validity.

We previously performed an observational study in 226 patients undergoing rhinoplasty [50] and found that 43% of aesthetic rhinoplasty patients showed moderate to severe BDD symptoms, defined as impairing and distressing thoughts and behaviour concerning their appearance [50]. In contrast, patients undergoing functional rhinoplasty or presenting to the ENT outpatient clinic for general ENT or otological concerns exhibited a moderate to severe BDD symptoms in only twelve percent and two percent of cases respectively [50]. Nevertheless, whereas 43% of aesthetic rhinoplasty patients showed moderate to severe BDD symptoms, only 2% met the diagnostic criteria for BDD. This rate, consistent with BDD rates reported in community samples, but much lower than the prevalence of BDD reported in cosmetic surgery patients, probably underestimates the true prevalence of BDD. Indeed, in the other patients, the nasal deformity was judged as observable and correctable by the aesthetic surgeon, excluding them to meet the diagnostic criteria for BDD [50]. This highlights the shortcoming of the present definition of BDD in a cosmetic setting, where the judgment of a slight defect in appearance seems to be highly subjective and may falsely exclude patients to meet the diagnostic criteria for BDD. This observational study also found a positive correlation between BDD symptom severity and the number of previous rhinoplasties and psychiatric history [50]. The latter emphasises the importance of a thorough preoperative assessment of cosmetic rhinoplasty patients, including a psychiatric history, as it might be an indicator for latent BDD. There was no significant correlation between age, gender, marital status, ethnicity, previous aesthetic surgery other than rhinoplasty, referral pattern, motivation for surgery and severity of BDD symptoms [50].

According to these findings, the first three items in the well-known acronym SIMON (single, immature, male, overly expecting and narcissistic) are not associated with an increased risk of BDD symptoms. In accordance to previous studies there was no correlation between the patients' and surgeons' evaluation of the nasal shape [43]. Moreover, whereas an inverse correlation between the severity of BDD symptoms and the patients' evaluation of his or her nose was found, there was no correlation between the observers' evaluation of the nasal shape and the severity of BDD symptoms [50]. This confirms that the degree of psychological distress is not related to the actual physical deformity but that it is related to and influences the patients' perception of his or her nasal shape. Finally, this observational study demonstrated that BDD symptoms have a clearly negative effect on daily functioning. Patients with more severe BDD symptoms had significant lower generic QoL and exhibited significantly more appearance-related disruption to everyday living, lower self-esteem, more difficulties with personal relations and emotional distress [50].

Only recently a large scale, prospective study in 166 patients seeking cosmetic rhinoplasty provided the first profound evidence that preoperative BDD symptoms have a clearly negative impact on the subjective outcomes after aesthetic rhinoplasty in terms of satisfaction with the final result and daily functioning [49]. Patients with more severe BDD symptoms before surgery, as assessed with the Yale-Brown Obsessive Compulsive Scale Modified for BDD (BDD-YBOCS), were significantly less satisfied with the final result after surgery. Moreover, after surgery, the subgroup of patients with moderate to severe BDD symptoms experienced significantly more impairment in daily functioning compared to patients with less severe or no BDD symptoms[49]. On the other hand, there was no correlation between patients' and surgeons' appraisal of nasal shape before or three months after surgery [49].

These findings confirm the long-standing impression that the prevalence of BDD and excessive BDD symptoms is much higher in patients presenting for aesthetic rhinoplasty, compared to that reported in the general population. Moreover, in every patient with excessive BDD symptoms, the indication of aesthetic rhinoplasty should be carefully evaluated, even when according to the aesthetic surgeon a nasal deformity is present, as it may result in a severely dissatisfied patient after the intervention.

RECOGNIZING BDD IN A COSMETIC SETTING

Literature on BDD and the awareness of aesthetic surgeons of this disorder have increased over the past decades. Nevertheless, diagnosing BDD during a preoperative consultation remains challenging. An electronic survey of the American Society for Aesthetic Plastic Surgery (ASAPS) demonstrated that 84% of plastic surgeons had treated a patient whom they believed was appropriate for surgery, only to realise after operation that the patient might have had BDD and was not a good candidate [9]. The same survey revealed that surgeons estimated that only two percent of patients seen for primary cosmetic surgery suffer from BDD. This rate, consistent with the prevalence of BDD in the general population but much lower than the prevalence of BDD reported in cosmetic surgery patients, suggests that most surgeons underestimate the prevalence of BDD in their patient population [9].

Missed diagnoses of BDD may be due to the lack of validated, easy-to-use screening tools for BDD in patients seeking aesthetic surgery [51]. We previously performed a systematic review through Medline and Embase to identify the existing screening tools for BDD in a cosmetic surgery setting [51]. In the majority of cases, general information and questions that might help in the identification of patients at risk for BDD [47,52,53] were provided. Only thirteen studies used a screening tool for diagnosing BDD in patients seeking cosmetic treatment. We identified six different screening tools. Two of them had been validated in a cosmetic dermatology setting: the Body Dysmorphic Disorder Questionnaire - Dermatology Version (BDDQ-DV) and the Dysmorphic Concern Questionnaire (DCQ) [51]. Both BDDQ-DV and DCQ are self-report tools that demand only limited effort of patients and therefore seem suitable for clinical use and large-scale research.

The BDDQ-DV is a modification of the Body Dysmorphic Disorder Questionnaire (BDDQ), a brief screening questionnaire for BDD that has been developed based on the definition of BDD in the Diagnostic and Statistical Manual of Mental Disorders, 4th Edition (DSM-IV) [16]. The BDDQ has been demonstrated to have a good sensitivity (100%) and specificity (89%) in a psychiatric setting [16]. Dufresne and Phillips modified this questionnaire for use in a dermatologic surgery setting (the BDDQ-DV) and tested its psychometric properties in this specific population [53]. The screening questionnaire was compared with the BDD-Diagnostic Manual and was used in combination with a five-point Likert defect rating scale (1: no defect - 5: severe defect). A positive screening for BDD was obtained if the patient acknowledged a preoccupation with his or her appearance and at least moderate (Likert rating scale ≥ 3) distress or impairment in functioning. A 100% sensitivity and 92.3% specificity was found in this particular population. The positive predictive value was 70% and the negative predictive value was 100% [53]. However, the validation process had several limitations. Firstly, the number of patients included was small ($n=46$), with seven patients diagnosed with BDD according to the BDD-DM. In a later stage, the BDDQ-DV was used in a larger cosmetic surgery population, but was no longer assessed against the gold standard for diagnosing of BDD, giving no further psychometric information of the BDDQ-DV [54]. A second limitation is that a dermatological surgeon and no mental health care worker confirmed the diagnosis of BDD.

The Dysmorphic Concern Questionnaire (DCQ) was constructed by Oosthuizen et al. (1998), based on the General Health Questionnaire (GHQ) [55]. It is a self-report instrument that consists of seven statements asking the respondent to rate their concern about their physical appearance and their attempts to deal with the problem relative to others (0=no concern, 3= much more than other people). The DCQ was originally developed to assess concern over physical appearance without the intent to diagnose BDD [55]. Stangier et al. evaluated the validity and reliability of the DCQ as a screening instrument for BDD in female dermatological outpatients [56]. In this study, the DCQ was assessed against the BDD-DM and the BDD-YBOCS. They found a high sensitivity when used in combination with an assessment of severity of the defect [56]. A cut-off value of greater than or equal to eleven appeared to be most suitable to recognise and screen for BDD (kappa coefficient 0.72, $p<0.001$, 100% sensitivity), whereas a cut-of value of more than or equal to fifteen appeared to be more appropriate to estimate the prevalence of BDD in a specific population (kappa coefficient 0.61, $p<0.001$, 100% specificity) [56]. According to the present instructions, both screening questionnaires should be used in combination with a defect rating scale, assessing the severity of the deformity. However, as mentioned previously, the judgment of a slight

defect in appearance is highly subjective in a cosmetic surgery setting. As a result, the outcome of both screening tools is also subject to interrater variability. Until now, no investigator independent screening tool has been developed. Moreover, no screening tool for BDD has been validated in a non-dermatological cosmetic surgery setting [51].

In two large-scale studies, the Yale-Brown Obsessive Compulsive scale Modified for BDD (BDD-YBOCS) was used to determine BDD symptom severity in patients seeking rhinoplasty [49,50]. This fully validated instrument represents the gold standard to assess the severity of BDD symptoms and consists of ten items rating BDD-related thoughts and behaviours [16,57]. Patients with moderate to severe BDD symptoms (i.e., BDD-YBOCS-score ≥ 16) were significantly less satisfied after cosmetic rhinoplasty and had more impairment in daily life compared to patients with no to mild BDD symptoms (i.e., BDD-YBOCS-score < 16), regardless of the objective deformity of nasal shape [50]. Therefore the BDD-YBOCS also seems to be appropriate to for use in the preoperative evaluation of aesthetic patients.

Finally, the use of computerised visual imaging might be helpful in the identification of patients with pathological body image, such as in BDD. Until now, no studies that determine the additional value of computerised visual imaging in patient selection have been performed.

CONCLUSION

BDD is a well-established psychiatric disorder that should be considered as a contraindication for cosmetic rhinoplasty. Given the high prevalence of BDD (symptoms) in a cosmetic rhinoplasty population and its clearly negative influence on the subjective outcomes after surgery, rhinoplasty surgeons should be familiar with BDD. In order to prevent patients from undergoing unsatisfying surgery and in the context of the increasing importance of medico-legal arguments, screening for BDD (symptoms) should be an integral part of the preoperative evaluation of cosmetic rhinoplasty patients.

DEVELOPMENT OF A SURGICAL NAVIGATION SYSTEM BASED ON 3D SLICER USING AUGMENTED REALITY (AR) TECHNOLOGY

Xiaojun Chen^{*}, PhD and Lu Xu

Institute of Biomedical Manufacturing and Life Quality Engineering,
School of Mechanical Engineering, Shanghai Jiao Tong University, Shanghai, China

ABSTRACT

Over the past decades, the field of computer-aided surgery has experienced tremendous development due to the rapid growth of computing power and the improvements in imaging modalities [1]. Based on the guidance of preoperative planning with CT, magnetic resonance imaging (MRI), or other volumetric image data associated with the patient, surgical navigation system is being widely used in various surgeries (ear, nose, oral implantology, etc.) for minimizing the risks and improving the precision of the surgeries [2]. Although some commercially-available surgical navigation systems have been approved for clinical applications, these systems are expensive and not open to the public. 3D Slicer is a free open source software platform for the research community of computer-aided surgery. In this contribution, a loadable module based on Slicer to support surgical navigation has been developed and validated. This research module allows reliable calibration of the surgical instruments, point-based registration and surface matching registration, so that the position and orientation of the surgical instrument can be tracked and displayed on the computer screen in real time to reduce the surgical risks. Furthermore, this module could be shared with global research community and be extended to various surgeries. On the other hand, Augmented Reality (AR)-based surgical navigation is a promising technology for clinical applications. For example, virtual anatomical structures such as soft tissues, blood vessels and nerves can be integrated with the real-world scenario in real time. In this study, an AR-based surgical navigation module (AR-SNS) is developed using an optical see-through HMD (head-mounted display), aiming at improving the safety and reliability of the surgery. With the use of this system, including the calibration of instruments, registration, and the calibration of HMD, the 3D virtual critical anatomical structures are aligned with the

actual structures of patient in real-world scenario during the intra-operative motion tracking process.

Keywords: computer-aided surgery, 3D Slicer, augmented reality, optical see-through HMD

1. INTRODUCTION

Percutaneous sacroiliac joint screw fixation is a kind of minimally invasive surgery for the clinical treatment of posterior pelvic ring injury. Compared with the traditional open reduction and internal fixation, the advantage of the screw insertion technique is that it brings less trauma, less intra-operative blood loss, low infection rate and necrosis rate, quick recovery, etc. However, in order to avoid injuring the peripheral nerves, blood vessels and soft tissues, it is important to control the position and orientation of screw through the intra-operative guidance. Currently, the major techniques include the X-ray C-arm system and computer-aided surgical navigation. Compared with the traditional X-ray C-arm system, the 2D or 3D computer-aided navigation system can improve the safety of sacroiliac joint screw insertion significantly and reduce the intra-operative X-ray fluoroscopy time.

Over the past decades, the field of computer-aided surgery has experienced tremendous development due to the rapid growth of computing power and the improvements in imaging modalities [1]. Based on the guidance of preoperative planning with CT, magnetic resonance imaging (MRI), or other volumetric image data associated with the patient, surgical navigation system is being widely used in various surgeries (ear, nose, oral implantology, etc.) for minimizing the risks and improving the precision of the surgeries [2]. Although some commercially-available surgical navigation systems have been approved for clinical applications such as Kick (Brainlab, Germany), StealthStation (Medtronic, USA), eNLight and NavSuite (Stryker Corporation, USA), Navigation Panel Unit (Storz, Germany) and etc., [3], the disadvantages include high-cost of the whole system and failure to clarify the several apparent issues pertaining to the calibration of the surgical instrument, registration, intra-operative motion tracking, etc. [2] In 2012, Daniel Behrendt (University of Leipzig, Germany), Martin Koestler (BrainLAB, Germany), et al. [4] evaluated 2D-navigaion and 3D-navigation for iliosacral screw fixation using the commercial computer-aided navigation systems (BrainLAB Trauma 2.6 and BrainLAB Spine & Trauma Fluoro-3D 1.6.0). However, the high cost of this navigation system restricts its wide clinical applications since it is not open to the public.

In this study, a powerful software package for visualization and medical image computing called Slicer, or 3D Slicer (Brigham Women's Hospital, Boston, MA) was used as a platform for developing a surgical navigation system. Unlike general commercial workstation, 3D Slicer is a free, open source software and is not required to specific hardware. The purpose of this study is to develop and evaluate a new loadable module named "Surgical Navigation System" (SNS) based on Slicer so that the risks of percutaneous implantation of sacroiliac joint screw surgery can be reduced in anatomically complex operation sites.

On the other hand, all of the traditional navigation systems use computer screen to render the navigation information such as the real-time position and orientation of the surgical instrument, virtual path of preoperative surgical planning, and etc., so that the surgeons have

to switch between the actual operation site and computer screen which is inconvenient and impact the continuity of surgery.

In recent years, due to the great development of Augmented Reality (AR) technology, more and more wearable AR devices have appeared like Google Glass, Skully AR-1 (An AR motorcycle helmet) [5], and etc. AR is an integrated technique of image processing, and in AR system, real objects and virtual (computer-generated) objects are combined in a real environment. Furthermore, real and virtual objects are aligned with each other, and run interactively in real time [6, 7]. Due to the advantages of AR visualization, developing a surgical navigation system based on AR is a significant challenge for the next generation. For example, after the registration of the preoperative CT in relation to the intra-operative realistic scene, surgeons can superimpose the virtual CT data onto the patient's anatomy [8]. In 2010, Liao et al. [9, 10] developed a 3-D augmented reality navigation system for MRI-guided surgery by using auto-stereoscopic images, and the system creates a 3D image, fixed in space, which is independent of viewer pose. In addition, Navab et al. [11] from Technical University of Munich have demonstrated a very practical application of AR. They developed an X-ray C-arm system equipped with a video camera, so that a fused image that combines a direct video view of a patient's elbow with the registered X-ray image of the humerus, radius, and ulna bones was produced.

This study also presents an AR-based surgical navigation module (AR-SNS) using an optical see-through HMD (head-mounted display), which encompasses the preoperative surgical planning, registration, and intraoperative tracking. With the aid of AR-SNS, the surgeon wearing the HMD can obtain a fused image that virtual anatomical structures such as soft tissues, blood vessels and nerves integrated with the intra-operative real-world scenario, so that the safety and reliability of the surgery can be improved.

2. MATERIALS AND METHODS

2.1. Surgical Navigation System Based on 3D Slicer

2.1.1. The Navigation Software Workflow Based on Slicer

Figure 1 shows the workflow and functions of the surgical navigation software based on Slicer (green) and the supporting algorithms and techniques (yellow). With the support of "SNS" module (pink) and some relevant modules from Slicer (blue), the 3D medical modeling, preoperative surgical planning, calibration of surgical instruments, registration, and intraoperative tracking can be realized. The framework of the software starts with loading of the preoperative CT data, and ends with the real-time navigation and its details described as follows:

- 1) Loading of the original CT data: The patient is imaged in the CT scanner, and the acquired images are automatically transferred to the Slicer interface via the "DICOM" module since Slicer allows loading images in DICOM format from disk or directly from the clinical Picture Archiving and Communication System (PACS).

Figure 1. The workflow and functions of surgical navigation software based on Slicer.

- 2) Image processing: Based on the CT data, each image can be segmented via the “Editor” module. Slicer provides different image segmentation methods for satisfying different requirements such as threshold segmentation and manual modification, so that the hard tissues and soft tissues can be marked.
- 3) 3D-Reconstruction: After image segmentation, a 3D surface model is reconstructed using the Marching Cubes algorithm [12]. All of the 3D modeling in this step is processed through the “Models” module of 3D Slicer.
- 4) Preoperative planning: Then, on the basis of these CT images and the 3D model, the user can implement preoperative surgical planning and 3D geometrical measurement via the Slicer ruler. When one target point and one entry point are selected, user can create a trajectory that connects these two points and adjust it in real-time. The virtual optimal path will be rendered on all of the 2D/3D views.
- 5) Communicate with optical tracking device: The Polaris Vicra optical tracking device can be activated and initialized via the “SNS” module.
- 6) Calibration of the surgical instruments: Since the Polaris optical tracking system only localizes the reference frame with mounted sphere-shaped retro-reflective markers, it is necessary to determine the spatial relationship between the surgical instrument and the reference frame (this procedure is also called as

“calibration”). Figure 2 shows a simulated surgical drill and a simulated surgical saw used in this research and the coordinate systems for the instrument and the reference frame are respectively established. The calibration encompasses three sections, “Pivot Calibration”, “Axis Calibration of surgical drill” and “Surface Calibration of surgical saw”, so that the movements of the reference frame can represent those of the surgical instrument.

- 7) Registration: The basic requirement of any navigation technique is the registration, which is the process of bringing two coordinate systems into spatial alignment [1]. In the most common clinical scenario, patient’s position must be registered (aligned) with preoperative image data set on the procedure table. There are a variety of registration methods including paired points [13-15] and surface matching [16, 17] concepts, which are proposed in this study. The details of registration are described below.

2.1.2. Calibration of the Surgical Instruments

The “Pivot Calibration” is to calculate the offset values of the tip point of the instrument. This procedure can be realized through the following method. Pivot the surgical instrument slowly around the tip for about half a minute in the Polaris optical tracking system. Then, on the basis of the collected data of about 250 frames regarding to the movements of the reference frame, the offset values can be calculated. As for the detailed description of the involved algorithms during this procedure, please refer to Ref. [18]. An open-source C++ software library named Image-Guided Surgery Toolkit (IGSTK) providing classes for implementing the standard “Pivot Calibration” [19, 20] is applied to “SNS” module, and the calibration data is automatically saved into an XML file. The orientation of the surgical drill is very important to the surgeons. Figure 3 shows a calibration tool used in this study for carrying out the “Axis Calibration of surgical drill”. There is a series of axial holes matched to the different drills. During the calibration process, the surgical drill is inserted into the matched axial hole, and the direction vector (u, v, w) of surgical drill relative to the coordinate system of reference frame can be obtained with the support of the tracking device (shown in Figure 4). According to (1), T_1 and T_2 are, respectively, the translation matrices of surgical drill’s reference frame and calibration tool relative to the tracking system, and $(1, 0, 0)^T$ is the direction vector of axial hole in the coordinate system of calibration tool.

$$(u, v, w)^T = T_1^{-1} T_2 \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix} \quad (1)$$

As for the “Surface Calibration of surgical saw”, Figure 5 shows the calibration. The handpiece of the saw lies on the two v grooves, and the blade is inserted into the slot of the calibration tool. The axial vector of the v groove and normal vector of the slot under the coordinate system of calibration tool are all known, and with the support of the tracking device, the normal vector $(u_x, v_x, w_x)^T$ and axial vector $(u_y, v_y, w_y)^T$ of surgical saw relative to the reference frame can be calculated as follows:

$$(u_x, v_x, w_x)^T = T_1^{-1} T_2 \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix} \quad (2)$$

$$(u_y, v_y, w_y)^T = T_1^{-1} T_2 \begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix} \quad (3)$$

According to (2) and (3), T_1 and T_2 are, respectively, the translation matrices of surgical saw's reference frame and calibration tool relative to the tracking system. $(1,0,0)^T$ and $(0,1,0)^T$ are, respectively, the normal vector of slot and axial vector of v groove in the coordinate system of calibration tool.

Since the quaternion is used in the XML file to presents the axial offset values while the initial calibrated results are vectors, we need to transform the vectors to a quaternion before running the tracking system. Based on the extension of Euler's formula, a quaternion (shown in (5)) can represents any rotation in three dimensions with an angle of rotation of θ around the axis defined by a unit vector see (4).

$$\vec{u} = (u_x, u_y, u_z) = u_x \mathbf{i} + u_y \mathbf{j} + u_z \mathbf{k} \quad (4)$$

$$q = \cos \frac{1}{2} \theta + (u_x \mathbf{i} + u_y \mathbf{j} + u_z \mathbf{k}) \sin \frac{1}{2} \theta \quad (5)$$

Suppose $\vec{v}$ is the obtained vector value when calibration step is completed:

$$\vec{v} = (\vec{v}_x \vec{v}_y \vec{v}_z) \quad (6)$$

And in this study, a 3D simulated instrument model is built along the negative direction of Z axis; thus:

$$\vec{z} = (\vec{z}_x \vec{z}_y \vec{z}_z) = (0, 0, -1) \quad (7)$$

Since the unit vector $\vec{u}$ equals the cross product of vector $\vec{v}$ and $\vec{z}$, based on the (8):

$$\begin{aligned} \vec{u} &= \vec{z} \times \vec{v} = \begin{vmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ z_x & z_y & z_z \\ v_x & v_y & v_z \end{vmatrix} \\ &= \begin{vmatrix} z_y & z_z \\ v_y & v_z \end{vmatrix} \mathbf{i} - \begin{vmatrix} z_x & z_z \\ v_x & v_z \end{vmatrix} \mathbf{j} + \begin{vmatrix} z_x & z_y \\ v_x & v_y \end{vmatrix} \mathbf{k} \end{aligned} \quad (8)$$

Hence:

$$\cos \theta = \frac{\vec{z} \cdot \vec{v}}{\|\vec{z}\| \|\vec{v}\|} = \frac{\vec{z}_x v_x + \vec{z}_y v_y + \vec{z}_z v_z}{\sqrt{z_x^2 + z_y^2 + z_z^2} \times \sqrt{v_x^2 + v_y^2 + v_z^2}} \quad (9)$$

So according to (8) and (9), $\vec{u}$, $\cos \frac{1}{2} \theta$, $\sin \frac{1}{2} \theta$ are all known, substitution of these results into (5) leads to the value of q . And the quaternion q can be finally written into the XLM file and be read when the Polaris optical tracking system is running.

2.1.3. Registration

Figure 6 shows the establishment of coordinate systems for real-time tracking in Slicer. There are four 3D coordinate systems, respectively, world coordinate system XYZ determined by the optical tracing system; virtual coordinate system $X_0Y_0Z_0$ (also referred as to the image coordinate system) determined by Slicer; reference coordinate system 1 $X_1Y_1Z_1$ (also referred as to the patient coordinate system) determined by the reference frame fixed on the patient; reference coordinate system 2 $X_2Y_2Z_2$ determined by the position probe. A_1 and A_2 are the transformation matrices with which Reference Coordinate System 1-2 can be, respectively, transformed to world coordinate system, and are all known through the Polaris optical tracking system. A_0 and A_{10} are the registration transformation matrices with which world coordinate system and reference coordinate system 1 can be, respectively, transformed to virtual coordinate system, and can be obtained through singular value decomposition (SVD) algorithm. Therefore, the spatial relationship among the various coordinate systems in navigation system can be determined, so that the movements of the patient and surgical instruments can be rendered in the preoperative image coordinate system in real time. As for the detailed principle of the point-based registration, please refer to [21].

In Slicer, the point-based registration step is accomplished using the “OpenIGTLinkIF”, “SNS”, “Annotation” and “Fiducial Registration” modules in 3D Slicer. The “OpenIGTLinkIF” module is a program module for network communication with external software/hardware using OpenIGTLink protocol. Therefore, with the support of this module, the optical tracking device can be connected, and it can implement the import and export of position, linear transform and image data between OpenIGTLinkIF-compliant software and MRML scene [22]. MRML scene is a coherent internal data structure that maintains the links between the individual medical image data types, their visualization and any other steady state of the application and modules. While the tracking device Polaris Vicra is communicated with Slicer through the “OpenIGTLinkIF”, the “SNS” will help the user to

obtain a list of fiducial coordinates in the realistic world that matched with the fiducials picked on the virtual image. Based on the two matched lists of fiducials in “Annotation”, the fiducial registration can be completed and the position and orientation of the surgical instrument model varies on the computer screen in real time so that the navigation procedure is realized.

Paul J. Besl and Neil D. McKay [23] described a general-purpose, representation-independent method based on the iterative closest point (ICP) algorithm for registration of 3-D shapes, which is widely used in the field of medical image registration. Therefore, in order to improve the registration precision, surface-based registration based on ICP is realized in “SNS” module. The principle of this method is seeking the closest measured point corresponding with target point set though the repeated iteration. It is an optimal matching algorithm based on the least square method, and the registration is accomplished while the value of objective function that residual sum of squares formed is less than the preset threshold. Figure 7 shows the point cloud on the STL model for surface registration which is collected on the pelvic model surface of patient by using the positioning probe.

Figure 6. The establishment of coordinate systems for real-time tracking in Slicer.

Figure 7. The point cloud for surface registration.

Figure 8. Using a positioning probe to collect the coordinates of the fiducial points.

2.1.4. Phantom Experiment

In order to evaluate the feasibility of the navigation system, a rapid plastic pelvis model is used for conducting a phantom experiment. First, a 3D model was reconstructed through the “Models” module based on the CT data. Then, the calibration of instruments including the positioning probe and the surgical drill were completed in the “SNS” module. After the Polaris optical tracking device was communicated with Slicer through the “OpenIGTLinkIF” module, the operator created a list in “Annotation” module including three fiducials whose coordinates were all initially at origin of a virtual coordinate system (VCS). Meanwhile, with the application of the Polaris and the positioning probe (shown in Figure 8), the coordinates

of the fiducials under the reference coordinate system (RCS) which was determined by the reference frame fixed on the pelvis model were also obtained. Using this two paired list of fiducial points (shown in Figure 9), a registration transformation matrix can be generated through the “Fiducial Registration” module and the movements of the surgical instruments now can be rendered in the preoperative image coordinate system in real time (see Figure 10). In addition, the “Volume Reslice Driver” module can reslice a volumetric image of the patient with the plane along the surgical tool and visualize the sectional image on the 2D and 3D viewer on the 3D Slicer window, which is particularly useful for stereotactic surgical navigation (also see Figure 10).

Figure 9. Two paired list of fiducial points.

Figure 10. The position of the drill is tracked and rendered on the computer screen.

2.2. The AR-Based Surgical Navigation Module (AR-SNS)

2.2.1. The Hardware Architecture of AR-SNS

The AR-SNS is constructed based on a high-performance graphical workstation (HP), a 2D LCD monitor (G2200W, BenQ), an optical tracking device (Polaris Vicra, NDI Inc., Canada) and an optical see-through HMD (nVisor ST60, NVIS, United States) (Shown in Figure 11). The workstation is equipped with a 4GB memory card, a core i7 CPU and an nVIDIA Quadro FX4800 graphic card, running on the windows 7 operating system. As for HMD, it uses high-resolution microdisplays featuring 1280×1024 24-bit color pixels per eye, for vivid visual rendering and integration with reality.

Figure 11. The hardware of AR-SNS.

2.2.2. 3d-Reconstruction and Preoperative Surgical Planning

Based on the original CT data, the segmentation of the hard tissue is conducted by using a threshold and region growing combined method, and for the soft tissue in each image, semi-automatic region growing method is adopted, and if it is over-segmented or under-segmented, manual modification is also used. Then, 3D surface models can be reconstructed through the marching cubes algorithm [12]. Figure 12 shows a 3D pelvis model and a bladder imported into AR-SNS after the 3D-reconstruction. All of the work including the image segmentation and 3D modeling is realized.

Figure 12. A 3D pelvis model and a bladder imported into the AR-SNS.

Figure 13. A virtual path for the surgical drill rendering on all of the 2D/3D views.

On the basis of these CT images and the 3D model, the procedure of preoperative planning can be implemented and is describe as follows: percutaneous implantation of sacroiliac joint screw is a very common surgery in orthopedics. And, in order to avoid injuring the important anatomical structures like soft tissues, blood vessels and nerves, a virtual path for the surgical drill should be created and will be rendered on all of the 2D/3D views. An example for a preoperative surgical planning is shown in Figure 13, so that the precision, safety and reliability of the implant surgery can be enhanced.

2.2.3. Calibration of the Patient's Position in Relation to the HMD

After registration, the preoperative images in HMD are aligned with the patient on the procedure table. Then, the calibration of HMD needs to be done. In the AR-SNS, the basic requirement is the calibration of the patient's position in relation to the HMD, which means the movement of the patient or the HMD will not affect the initial correspondence of VCS and RCS. The principle is described as follows: first of all, two reference frames are respectively mounted on the HMD and patient. Then, in order to obtain the calibration matrix after the initial registration of the patient's position in relation to the image data set, we built the transformation relationship shown in Figure 14. Suppose:

R is the initial transformation matrix of VCS to reference frame coordinate system2;

A_1 and A_2 are respectively the transformation matrix of reference frame coordinate system1 to the World Coordinate System before and after movement of the user head;

A_3 and A_4 are respectively the transformation matrix of reference frame coordinate system2 to the World Coordinate System before and after movement of the patient;

B_1 is the matrix of virtual model under the VCS before movement;

B_2 is the calibration transformation matrix of virtual model under the VCS;

Since the relative position of one point on the computer virtual image is fixed before and after movement, setting X as the coordinate of this point in computer virtual image coordinate system. Then, X_1 is the coordinate of X in VCS (also referred as the computer screen coordinate system) before movement and X_2 is the coordinate of X in VCS after movement. Equations (1) and (2) demonstrate the transformational relation:

$$RB_1X = X_1 \quad (1)$$

$$RB_2X = X_2 \quad (2)$$

The purpose is to maintain the relative position of this point in patient coordinate system unchanged before and after movement, so setting X_3 as the coordinate of X in reference frame coordinate system2. Equations (3) and (4) show the transformational relation before and after movement:

$$(A_3)^{-1}A_1X_1 = X_3 \quad (3)$$

$$(A_4)^{-1}A_2X_2 = X_3 \quad (4)$$

Thus, based on Equations (1), (2), (3) and (4):

$$B_2 = [(A_4)^{-1}A_2R]^{-1}(A_3)^{-1}A_1RB_1 \quad (5)$$

In the polaris optical tracking system, seven elements representing the unit quaternion and the translation vector, are used to describe the transformation of a rigid body under world coordinate system. Therefore, A_1 , A_2 , A_3 , and A_4 can be calculated on the basis of each rigid body's seven elements provided by the Polaris, and R can be calculated through the point-based registration and surface registration respectively under patient coordinate system and virtual coordinate system.

Since A_1 , A_2 , A_3 , A_4 , R , B_1 (which can be supposed as an identity matrix) are all known, the calibration transformation matrix B_2 can be calculated according to equation (5). As a result, the position and orientation of the virtual model will change with corresponds to the movement of HMD and patient, and match the real anatomical structures during intra-operative navigation procedure.

The setup of the AR-SNS and the actual view seen from the HMD is also illustrated in Figure 15.

2.2.4. Phantom Experiment and Cadaver Experiment

A phantom experiment was first conducted. With the original CT data (0.625 mm slice thickness, 512×512 matrix), a 3D pelvis model was reconstructed through the threshold segmentation, and fabricated using 3D printing technology. Then, the critical anatomical structures (especially the soft tissues, blood vessels and nerves) can be segmented using the manual modification method. In this experiment, a 3D bladder and some blood vessels and nerves were reconstructed. After calibration and registration, the AR-based surgical navigation was realized. Seen through the HMD, the 3D virtual anatomical structures were aligned with the real plastic pelvis model in any time regardless of the movement of HMD and model. (see Figure 15)

Figure 14. The establishment of coordinate systems in AR-SNS.

Figure 15. Wearing HMD to conduct a phantom experiment.

Figure 16. The panoramic view of the operating room for a cadaver experiment.

Researchers have also conducted a cadaver experiment for percutaneous implantation of sacroiliac joint screw in an operating room. First of all, five titanium miniscrews were inserted into the pelvis before CT scanning for fiducial point registration. Then, based on the CT data, 3D-reconstruction and preoperative surgical planning were conducted, and the data were imported to AR-SNS. Figure 12 shows the 3D-reconstruction, including a pelvis model, a bladder model and titanium miniscrews models. In addition, the optimization design of a virtual drill trajectory is the preoperative planning result. (see Figure 13) Then, in order to show the position and orientation of the surgical drill model correctly, point calibration and axis calibration were carried out. After point-based and surface matching registration and calibration of the HMD, the 3D virtual bladder was aligned with the real cadaveric pelvis during the intra-operative, and the 3D instrument model is displaying in HMD in real time, so that the operator can implant the sacroiliac joint screw into the pelvis along with the preoperative planned trajectory. (see Figure 16)

CONCLUSION

Nowadays, the minimally invasive surgery is becoming more and more popular in orthopaedics. Percutaneous implantation of sacroiliac joint screw is a typical surgery to treat the posterior pelvic ring injury. Nevertheless, due to the anatomic intricacies of the pelvis and the screw length, it is still a challenge to control the intra-operative position and orientation of the screw for avoiding damaging the surrounding critical anatomical structures. Furthermore, the radiation exposure of the conventional technique using intra-operative X-ray C-arm system is excessive. In the past years, an image-guided system developed by the Brainlab AG company was performed and evaluated on the transiliosacral screw fixation surgery, aiming at minimizing the surgical risks. However, this commercial navigation system is expensive and the lack of software expandability is obvious. As a result, the individual requirements of the surgeons cannot be met. Compared with some commercial visualization and medical image processing software, 3D Slicer (or just Slicer) is a free open source software platform for the community of computer-aided surgery, and it supports the development of extension modules. Although many researcher groups have presented the surgical navigation systems based on Slicer for various surgeries in the literature, their applications in percutaneous sacroiliac joint screw fixation are rarely reported.

In this contribution, a new loadable module (“SNS” module) based on Slicer was developed to achieve computer-aided navigation, aiming at improving the safety of percutaneous sacroiliac joint screw fixation surgery. The presented software module allows the calibration of surgical tools including “Pivot Calibration”, “Axis Calibration of surgical drill” and “Surface Calibration of surgical saw”, high-accuracy registration (point-based and surface matching), intra-operative motion tracking and virtual intra-operative CT imaging. The implementation and workflow of the designed Slicer module has been described in detail and validated through a cadaver experiment. With the support of other modules like “Editor”, “Models”, “OpenIGTLinkIF”, “Fiducial Registration”, etc., image segmentation, 3D-reconstruction, preoperative surgical planning, registration and intra-operative motion tracking can all be realized in Slicer. In addition, the “SNS” module can also be extended to various surgeries such as ear, nose, throat and oral implantology, and will be open-sourced to the global research community.

On the other hand, the Augmented Reality technology has great potential to apply to the computer-aided surgical navigation system. Some examples of AR-based surgical applications have been presented in the literature, for example, a hybrid tracking method for surgical augmented reality (University of Tübingen, Germany), an integral videography system (University of Tokyo, Japan), an alternative biopsy guidance system (University of Pittsburgh, America), an X-ray C-arm system (Technical University of Munich, Germany), etc. In addition, the calibration of AR device is also introduced in some reports. For instance, Falko Kellner (University of Kiel, Germany) et al. proposed a calibration approach with optical see-through head mounted displays to improve the average distance judgment of users in 2012, but, there is a significant underestimation of distances in the virtual environment [24]. Yakup Genc (Siemens Corporate Research Imaging and Visualization Department, America) et al. developed a method to calibrate stereoscopic optical see-through HMDs based on the 3D alignment of a target in the physical world with a virtual object in user’s view [25]. However, the calibration algorithm was only validated on a video see-through system, and the

researchers did not validate it for the optical see-through system. Stuart J. Gilson (Department of Physiology, United Kingdom) placed a camera inside an optical see-through HMD to take pictures simultaneously of tracked object and features in the HMD display for performing camera calibration [26]. In this study, a method for calibrating an optical see-through HMD is introduced and validated on an optical see-through system, and a surgical navigation system based on AR has been developed.

With the use of this system, including 3D-reconstruction, preoperative planning, registration, and calibration of HMD, the 3D virtual critical anatomical structures are aligned with the actual structures of patient in real-world scenario during the real-time motion tracking process. Therefore, some disadvantages of the traditional surgical navigation (For example, surgeon is no longer obliged to switch between the real operation scenario and computer screen) are overcome, and the safety, accuracy, and reliability of the surgery may be improved. The cadaver experiment validates the feasibility of AR-SNS. However, it is just a pilot study and still under development. Furthermore, some other experiments will be conducted to test the accuracy and efficiency of this system. The typical method is to measure the average distance deviations between the preoperative surgical planning trajectory and postoperative CT data. The researchers from Germany recently have compared the accuracy of a navigation system for oral implantology using either a head-mounted display or a monitor as a device for visualization. The results show that using of an HMD has no major disadvantages compared to the monitor setting [27].

Chapter 45

APPLICATION OF NAVIGATION SYSTEM IN BIMAXILLARY SURGERY

Sun Yi and Constantinus Politis*

Stomatology and Maxillofacial Surgery,
KU Leuven University

ABSTRACT

Perioperative navigation is an upcoming tool in orthognathic surgery. This chapter contains two parts. The aim of this chapter is to evaluate the accuracy of image-guided maxillary positioning in the sagittal and vertical directions. 18 patients (12 males, 6 females) underwent bimaxillary surgery with the use of perioperative navigation. During Le Fort I osteotomy, the Kolibri™ surgical navigation system was used to control movement of the maxilla at the edge of the central upper incisor in the sagittal (buccal surface) and vertical (incisal edge) direction. At one week after surgery, a postoperative lateral cephalogram was taken and was registered to the preoperative lateral cephalogram to identify the actual surgical movement of the maxilla. Student's two-tailed paired t-test was used to evaluate differences between the planned and actual surgical movement of the maxilla, which were 0.63 ± 0.50 mm ($p = 0.12$) in the sagittal direction and 0.57 ± 0.37 mm ($p = 0.45$) in the vertical direction. Our findings show that the navigation system is a useful perioperative tool to control the surgical change of the maxilla in bimaxillary surgery.

Keywords: perioperative navigation, anatomic landmark-based registration, accuracy of image-guided maxillary positioning

INTRODUCTION

Precise positioning of the maxilla is an important determinant of the aesthetic and functional outcomes of orthognathic surgery. Bimaxillary surgery is usually performed in two

* Corresponding Author's Email: constantinus.politis@uzleuven.be.

phases to achieve proper positioning: the preoperative surgical planning and intermediate splint construction, followed by the precise positioning of the maxilla during surgery with the help of the pre-fabricated intermediate and final splints.

Previous studies have shown that a number of inaccuracies can occur during facebow registration, transferring the facebow data to the articulator, and model surgery to fabricate the intermediate splint. Several different methods have been introduced to improve the accuracy of the intermediate splint [1, 2, 5, 6, 16, 17, 25, 26]. Recently, the concept of computer-assisted virtual surgical planning has been introduced. Different methods have been developed to simulate the cut of the jaws, and to virtually place the upper and lower jaws into the desired position [4, 13, 23, 24, 27]. The digital intermediate splint and the final splint are then fabricated through CAD/CAM technology. These rapid prototyping splints have a high degree of accuracy compared to conventional manually fabricated splints [8].

The principle behind the surgical technique has not changed over the past twenty years. During bimaxillary surgery, when the maxilla is mobilized first, the vertical change of the maxilla can be controlled using an intraoral reference point (IRP) [10] or an extraoral reference point (ERP) [7, 9, 11, 15, 18, 19]. Both methods have been proven to have good accuracy in the vertical direction. Regarding the transversal plane, precision relies on the use of the intermediate splint to position the maxilla as planned. The mobility of the temporomandibular joint (TMJ) can potentially lead to inaccuracies, especially in the sagittal direction, and it is sometimes very difficult to achieve full control of, e.g., a multi-segmented maxilla in all dimensions. Therefore, even a good intermediate splint is not always sufficient to precisely position the maxilla in the sagittal direction. There is currently no simple perioperative tool that allows the surgeon to control the surgical change of the maxilla during the operation, especially in the sagittal direction.

Navigation systems are widely used in the operating room to improve surgical accuracy. Bell [3] previously reported the clinical outcome of image-guided orthognathic surgery; however, the accuracy of the surgery was not quantified. The purpose of this chapter is to evaluate the accuracy of image-guided maxillary repositioning in the sagittal and vertical directions.

MATERIALS AND METHODS

18 patients (12 males, 6 females) underwent bimaxillary surgery with perioperative use of the KolibriTM navigation system (Brainlab AG, Feldkirchen, Germany). A preoperative lateral cephalogram was obtained four weeks before the operation. Surgical treatment was planned based on cast model study, clinical examination and lateral cephalogram tracing. All patients were scheduled for a one-piece Le Fort I osteotomy with a bilateral sagittal split osteotomy (BSSO) of the lower jaw as a second step during the bimaxillary procedure. Wax bite registrations were taken with the teeth in centric relation, followed by facebow registration. Model surgery following the surgical treatment plan was performed on the ARH articulator (Dentatus, Spanga, Sweden). One week before surgery, an intermediate splint was manually fabricated, which was placed inside the patient's mouth on the evening before the operation to ensure that it correctly fit on the occlusal surface.

Each patient was scanned using a SkyView (Cefla dental, Imola, Italy) cone beam computed tomography (CBCT) scanner four weeks before the operation using the following parameters: 9-inch field of view and dentition mode. Each slice was composed of 512×512 pixels, and the voxel size was $0.3 \times 0.3 \times 0.3$ mm. The DICOM (Digital Image Communications in Medicine) data was imported into the iPlan ENT 3.0.0 surgical planning software (Brainlab AG, Feldkirchen, Germany). In this program, the Frankfort horizontal plane (FHP) was orientated as the X-Y plane and the nasion perpendicular plane was orientated as the Y-Z plane. The following six anatomical landmarks were selected for point-based registration: the left and right infraorbital foramen, the anterior nasal spine, the tips of the left and right upper canines, and the mesial contact points of the left and right upper incisors (Figure 1). The prepared surgical planning was transferred to the navigation system via USB stick.

The navigation system was set up in a standard operating room. The preoperative CBCT images were displayed on the monitor of the navigation system. With the patient under general anesthesia, the reference star array was securely attached to the patient's skull with a fixation screw (Figure 2). At the beginning of the operation, an experienced surgeon performed patient-to-image registration, following the protocol described by Sun et al [22]. After patient-to-image registration, when the tip of the VectorVision² Pointer (Brainlab AG, Feldkirchen, Germany) was placed on a specific anatomic landmark, the position of the pointer tip in the patient space was calculated automatically through the navigation system and transferred to the corresponding position in the preoperative CBCT image space. The position of the pointer tip was projected on the preoperative CBCT image as a green cross.

Figure 1. Six anatomical landmarks were indicated in the planning software (iPlan ENT 3.0.0): the left and right infraorbital foramen, the anterior nasal spine, the tips of the left and right upper canines, and the mesial contact point of the left and right upper incisors.

Figure 2. The reference star array was securely attached to the skull of the patient.

The VectorVision² Pointer was used to ensure the accuracy of the registration on the following anatomic points: the tips of the left and right upper canines and the upper incisors. The VectorVision² Pointer was also used to mark a reference point at the tip of the central upper incisor, which appeared as blue dot on the CBCT image in the navigation system. Registration was accepted if no discrepancy was observed between pointer position in the surgical field and the position of the green cross in the CBCT dataset.

A Tekka screw was inserted at the base of nose. After the down-fracture of the maxilla, intermaxillary fixation was applied using the intermediate splint to reposition the maxillary teeth in the desired occlusion. While the intermediate splint allowed the surgeon to place the maxilla at the desired position in the transversal and sagittal planes, the vertical position was dictated, not by the intermediate splint, but rather by manual intrusion or extrusion rotation on the condyle of the mandible. The vertical change of the maxilla was first controlled using a caliper by repeated measurement of the distance between the Tekka screw and the edge of the upper incisor before and after maxillary positioning.

The VectorVision² Pointer was then used to check the vertical change at the edge of the upper central incisor. The pointer was physically positioned at the edge of the central incisor. The axis of the pointer was then orientated perpendicular to the FHP. On the preoperative CBCT image, coming from the green cross, which represented the pointer tip, an offset along the vertical direction was set until it (red cross) reached the edge of the upper central incisors (Figure 3).

The amount of the offset was noted as the surgical change in the vertical direction. The minimum offset was 1 mm. When there was a discrepancy between the vertical measurements from the caliper and the pointer, the measurement of the navigation system was preferred.

Figure 3. The blue point was acquired at the edge of the upper central incisor after the patient-to-image registration. After Le Fort I osteotomy, to measure the vertical movement of the maxilla using the navigation system, the pointer tip was physically positioned at the edge of the upper central incisor. The axis of the pointer was orientated perpendicular to the FHP. In this example, the pointer tip was projected on the preoperative CBCT image as green cross. The pointer offset was 4 mm along the vertical direction until it (red cross) reached the edge of the upper central incisor in the preoperative CBCT image. The figure illustrated that the surgical change in the vertical direction was 4mm. (From Sun Y, Luebbers HT, Agbaje JO, Lambrichts I, Politis C. The accuracy of image-guided navigation for maxillary positioning in bimaxillary surgery. *J Craniofac Surg* 2014;25(3):1095-9).

To check the surgical movement of the maxilla in the sagittal direction, the pointer was physically positioned at the edge of the central incisor. The axis of the pointer was then orientated parallel to the FHP. On the preoperative CBCT image, coming from the green cross, which represented the pointer tip, an offset along the sagittal direction was set until it (red cross) reached the edge of the upper central incisors (buccal surface) (Figure 4).

Figure 4. After Le Fort I osteotomy, to measure the sagittal movement of the maxilla using the navigation system, the pointer tip was physically positioned at the edge of the upper central incisor. The axis of the pointer was orientated parallel to the FHP. In this example, pointer tip was projected on the preoperative CBCT image as green cross. The pointer offset was 4 mm along the sagittal direction until it (red cross) reached the edge of the upper central incisor (buccal surface) in the preoperative CBCT image. The figure illustrated that the surgical change in the sagittal direction was 4mm. (From Sun Y, Luebbers HT, Agbaje JO, Lambrichts I, Politis C. The accuracy of image-guided navigation for maxillary positioning in bimaxillary surgery. *J Craniofac Surg* 2014;25(3):1095-9).

The amount of the offset was noted as the surgical change in the sagittal direction. The minimum offset was 1 mm. Since the sagittal position of the maxilla is also determined by the manual compression exerted on the condyle during maxillary repositioning over the intermaxillary fixation, small sagittal corrections could be made until the pointer indicated that the preplanned sagittal position of the upper incisor was reached. The maxilla was then held in the desired position and stabilized with four osteosynthesis plates, which were adapted

to allow for passive placement without displacement of bone during fixation of the osteosynthesis screws. Once the upper jaw was stabilized, the navigation system was used to re-check the surgical movement in the sagittal and vertical directions at the edge of the upper central incisors. This final measurement from the navigation system was recorded for each patient.

At one week after surgery, a postoperative lateral cephalogram was obtained. Surgically unaffected structures of the skull base were used to superimpose the preoperative cephalogram tracing onto the postoperative lateral cephalogram image. The sagittal direction was defined by the preoperative FHP. The vertical direction was perpendicular to the FHP. The actual surgical movement at the edge of central incisor point of the maxilla was measured separately in the sagittal and vertical directions. These measurements were repeated four weeks later by the same observer. For each patient, the actual surgical movement was calculated over these two measurements.

Statistical analysis was performed using MedCalc (MedCalc Software bvba, Belgium). Student's two-tailed paired *t*-test was performed to determine intra-observer reliability; as well as to make comparisons between the planned and the actual surgical movement of the maxilla in the sagittal and vertical directions, and between the measurement results from the navigation system and the actual surgical movement in the sagittal and vertical directions. Differences were considered statistically significant if $p \leq 0.05$.

RESULTS

The preoperative surgical planning included movement of 2 to 6.5 mm in the sagittal direction (defined as advancement/setback) and movement of -8.5 to 4.5 mm in the vertical direction (defined as intrusion/extrusion), with advancement and extrusion represented by movement in the positive direction.

Patient-to-image registration was successful and uneventful in all patients. Evaluation of intra-observer reliability revealed no significant differences between the two measurements based on cephalographic images: sagittal ($p = 0.27$) and vertical ($p = 0.14$). The absolute mean differences between the first and the second measurements were 0.14 mm and 0.16 mm in the sagittal and vertical directions, respectively. In the sagittal direction, the absolute mean difference between the planned and the actual surgical change was 0.63 ± 0.50 mm (0.1 – 2.1 mm; $p = 0.12$). The absolute mean difference between the measurement result from the navigation system and the actual surgical change was 0.47 ± 0.33 mm (0.1 – 1.27 mm; $p = 0.19$). The absolute mean difference between the preoperative surgical planning and the measurement result from the navigation system was 0.33 ± 0.45 mm (0 – 1 mm) (Table 1).

In the vertical direction, the difference between the measurement with the caliper and the measurement from the navigation system was more than 1 mm in two out of 18 patients. The absolute mean difference between the planned and the actual surgical change was 0.57 ± 0.37 mm (0 – 1.1 mm; $p = 0.45$). The absolute mean difference between the measurement result from the navigation system and the actual surgical change was 0.64 ± 0.41 mm (0 – 1.54 mm; $p = 0.94$). The absolute mean difference between the preoperative surgical planning and the measurement result from the navigation system was 0.17 ± 0.30 mm (0 – 1 mm) (Table 2).

Table 1. Distribution of the differences between the surgical treatment plan, measurement results from the navigation system, and actual surgical change at the edge of the upper central incisor in the sagittal direction (n = 18)

	Range (mm)				Absolute mean ± SD (range) in mm
	0-0.5	0-1	0-1.5	>1.5	
Planned - actual	10 (55.6%)	15 (83.3%)	17 (94.4%)	1 (5.6%)	0.63 ± 0.50 (0.1-2.1)
Navigation - actual	12 (66.7%)	16 (88.9%)	18 (100%)	0 (0%)	0.47 ± 0.33 (0.1-1.27)
Planned - navigation	13 (72.2%)	18 (100%)	18 (100%)	0 (0%)	0.33 ± 0.45 (0-1)

Table 2. Distribution of the differences between the surgical treatment plan, measurement results from the navigation system, and the actual surgical movement at the edge of the upper central incisor in the vertical direction (n = 18)

	Range (mm)				Absolute mean ± SD (range) in mm
	0-0.5	0-1	0-1.5	>1.5	
Planned - actual	8 (44.4%)	17 (94.4%)	18 (100%)	0 (0%)	0.57 ± 0.37 (0-1.1)
Navigation - actual	6 (33.3%)	17 (94.4%)	17 (94.4%)	1 (5.6%)	0.64 ± 0.41 (0-1.54)
Planned - navigation	17 (94.4%)	18 (100%)	18 (100%)	0 (0%)	0.17 ± 0.30 (0-1)

DISCUSSION

Successful orthognathic surgery requires repositioning the maxilla as precisely as possible in accordance with the preoperative surgical planning. The surgical accuracy at the anterior maxilla, especially at the incisor tip, is very important for aesthetic reasons, as small inaccuracies of the upper incisor position can affect the patient's satisfaction, particularly if they occur in the vertical position.

The ERP technique used to control the vertical change of maxillary repositioning is highly precise, with previous studies reporting maxillary positioning vertical deviations of between 0.37 and 1 mm [7, 11, 15, 18, 19]. In our study, the surgical change of the maxilla was controlled by the navigation system, and we observed a variation of 0.57 ± 0.37 mm in the vertical direction between the preoperative surgical plan and the actual surgical movement, which was comparable to previous studies using the ERP method.

A most recent study by Gil et al., [9] reported an even better accuracy of 0.3 ± 0.20 mm in the vertical direction using medial canthal region as an ERP. In another study [10], where an improved internal reference point (IRP) technique was applied, 81% of the patients showed a variation of within 0.4 mm in the vertical direction.

There is typically a larger deviation in the sagittal direction. Polido et al [19] reported that the average deviation of sagittal maxillary positioning was about 1.7 mm, which was greater than the deviation in the vertical positioning (1 mm). Ong et al., [15] reported a mean difference of 0.85 mm between the planned and the actual surgical movement in the sagittal direction. Similarly, Kretschmer et al., [11] found a median difference of 1 mm between the planned and the actual surgical movement in the sagittal direction. Deviation in the sagittal direction is likely due to several sources of error: errors associated with the facebow recording, transferring face bow to the articulator, model surgery to fabricate the intermediate splint and the mobility of the TMJ [20, 28]. The present study showed that image guidance improved the deviation in the sagittal direction to a mean of 0.63 mm (0.1–2.1 mm). Omura et al. [14] described another method of joint fixation with positioning plates to improve the accuracy of the maxillary positioning; however, this technique required an additional surgical procedure and it is difficult to manage during surgery. Kretschmer et al., [11] mentioned the clinical outcome of a similar technique, in which 75.2% of the deviations were within 1 mm in both the sagittal and vertical directions. In our study, 83.3% of the patients showed a variation of within 1 mm between the planned and the actual movement of the maxilla in the sagittal direction. This finding was comparable to those mentioned by Kretschmer et al [11] and was better than those reported by Polido et al., [19] (39%) and Stanchina et al., [21] (65%).

In our study, the average deviations between the measurement results from the navigation system and the actual surgical movement were within 0.65 mm in both the sagittal and vertical directions. There were no significant differences between the measurement results of the navigation system and the actual surgical movements in both the sagittal and vertical directions. These findings prove that the navigation system can directly assess the surgical movement of the maxilla in the operating room, and thus has the potential to eliminate the errors associated with facebow recording, transferring face bow to the articulator, model surgery to fabricate the intermediate splint and the mobility of the TMJ.

It must be noted that image-guided surgery can introduce additional errors. Firstly, the navigation system only reports the Euclidian distance between the tip position of the pointer in the world space and the target label in the imaging space. This direct measurement provides no clinically relevant information, it is more important to know the surgical change in sagittal/vertical direction respectively. To identify the surgical change in the sagittal direction, it is necessary to orientate the axis of the pointer parallel to the FHP. Similarly, to evaluate the vertical change of the maxilla, the axis of the pointer needs to be orientated perpendicular to the FHP. Because of the limited space in the oral cavity, it is almost impossible to perfectly measure the sagittal and vertical changes through the pointer, especially in the posterior regions of the maxilla. Additionally, during the operation, the minimum offset unit of the pointer is 1 mm. The surgeon can only estimate the surgical change to up to half of the minimum offset unit, meaning that the maximum accuracy of the measurement is 0.5 mm.

Human-related errors can occur in image-guided surgery, because it is difficult to keep the maxilla stable during maxilla fixation. Even under the guidance of the navigation system, it is difficult to avoid maxillary positioning errors during fixation of the osteosynthesis plates when eccentric drilling occurs or if the plates are not perfectly adapted to the bone in a passive way. Such error may reduce the accuracy of maxillary positioning in the sagittal direction. In our study, the maximum difference between the preoperative planning and the final measurement from the navigation system was within 1 mm.

Finally, the accuracy of the image-guided surgery is mainly defined by the target registration error (TRE). In our study, six anatomic landmarks were selected for patient-to-image registration, and we found maximum differences between the measurement results from the navigation system and the actual surgical movement of 1.27 mm and 1.54 mm in the sagittal and vertical directions, respectively. Sun et al [22] used this method in an *in vitro* study with the same anatomic landmarks selected for paired point-based registration; similar to our findings, they found the mean TRE in the region of the maxilla to be 0.93 ± 0.31 mm, and the maximum TRE observed was 1.6 mm in the region of frontal maxilla. The TRE is one factor that limits the accuracy of image-guided surgery. In an ideal situation where physical error sources can be eliminated, the navigation system can give the surgeon confidence that the deviation between the planned and the actual surgical movement can be controlled within the range of the maximum TRE. To improve the accuracy of maxillary repositioning, other image registration techniques could be applied to diminish the TRE, e.g., template-based registration or fiducial screws can be inserted in the maxilla for point-based registration. Luebbbers et al [12] reported a maximum TRE of 0.9 mm in the periorbital region using a maxillary splint with only two fiducial screws inserted percutaneously on the lateral orbital rim. This registration technique is the most accurate among all previously studied techniques; however, additional surgical work is required and the procedure causes pain and discomfort to the patient.

The following issues should be considered when performing image-guided surgery: the set-up and use of the image-guided navigation system added 30–45 minutes to the surgical treatment time. The navigation star array is fixed on the skull and could possibly cause infection after the operation, although this seems unlikely.

CONCLUSION

In conclusion, our study demonstrates that intraoperative computer navigation combined with the use of intermediate splint is a useful additional tool for controlling the surgical change of the maxilla in bimaxillary surgery, enabling precise positioning of the maxilla during bimaxillary surgery. Overall, we find that a navigation system might be helpful for controlling the final surgical outcome during the operation, especially for non-experienced surgeons.

COMPUTER-ASSISTED MINIMALLY INVASIVE SURGERY: IMAGE-GUIDED INTERVENTIONS AND ROBOTIC SURGERY

Francisco M. Sánchez Margallo* and Juan A. Sánchez Margallo

Jesús Usón Minimally Invasive Surgery Centre, Cáceres, Spain

ABSTRACT

Laparoscopic surgery represents one of the main evolutions of surgical techniques. However, this leads to some challenges that can be reduced through computer technology. This chapter presents a review of the state of the art of current methods for computer-assisted in laparoscopic surgery. Surgical navigation systems have the potential to improve information on the exact place of key anatomical structures such as vessels and tumors within the surgical field. With the support of navigation systems surgeons can potentially improve clinical outcomes of image-guided interventions. The use of image guidance methods such as augmented reality and near infrared fluorescence enhances visual information to supplement the two-dimensional imaging and the absence of tactile feedback in laparoscopic surgery. In the field of robotic surgery, robotic systems enable surgeons to perform advanced laparoscopic procedures with greater visualization and dexterity than traditional laparoscopic technology. Image-guided robots can be inserted into the patient's body by using real-time feedback from different imaging techniques. Recent developments in minimally invasive techniques have led to laparoendoscopic single-site surgery (LESS), which has a great potential in patient outcomes but remains technically challenging. Several robotic-assisted systems have been applied to single-site surgery to deal with these limitations. This has resulted in a new kind of surgery, robotic LESS or R-LESS. This work gives an overview of current developments in image-guided laparoscopic interventions regarding navigation systems and image guidance methods, as well as in new systems and applications of robotic surgery, especially in novel surgical techniques such as LESS and NOTES.

1. INTRODUCTION

The introduction of minimally invasive surgery (MIS) has been one of the greatest advances in the surgical field in recent times. This kind of surgery tries to reduce the invasiveness for the patients, providing them with several benefits such as reduction of tissue trauma and postoperative pain, better aesthetic results, and less operative periods with the consequence reduction of the healthcare costs. These benefits have made these surgical techniques the focus of attention and the choice in many surgical procedures, which usually

have been performed by open surgery. However, they have some limitations that should be addressed. In minimally invasive procedures the depth perception is lost, and surgeons have to perform the intervention using a two-dimensional (2D) interpretation of the surgical field. Besides, they have to use new surgical instruments that in most cases limit their surgical skills and hamper the ergonomic conditions during surgery. All the previous restrictions entail a steep learning curve for the surgeon.

Continuous advances in computer science make computer-assisted surgery (CAS) a new powerful way for addressing some of the aforementioned limitations, increasing and expanding surgeon's perceptions. The broad range of CAS represents the integration of computer technology in surgical procedures for presurgical planning, surgical guiding as well as surgical manipulation. Within the field of CAS, image-guided surgery (IGS) and surgical robots are the most challenging fields. Image-guided surgery provides surgeons with tools to apply preoperative information from the patient during the surgical performance as well as the possibility of preoperative planning. This allows the surgeon to determine the best way to tackle an operation and to treat a disease, and later use this information as support during the course of the intervention. Similarly, advances in robot technology have enabled the development of robotic surgical systems and devices for surgical assistance. These systems are created as tools to solve certain technical difficulties during the performance of some MIS techniques, providing three-dimensional (3D) view of the surgical field, improvement of the surgical instruments, increased surgical skills, improving ergonomics, and even providing tactile feedback during surgery. The objective of this chapter is to review the history and current status of computer-assisted in MIS. The chapter is organized into two main sections, which are focused on IGS and robotic-assisted surgery, as main components of CAS.

2. IMAGE-GUIDED SURGERY

In order to cope with some of the limitations in MIS and guide the surgeon during a surgical procedure, systems for IGS have been developed. The lack of tactile feedback and 3D sensation in video-assisted surgery accelerated the need for these systems. In addition, for the human eye, several pathologies, such as the presence of non-superficial tumors, are not easily distinguishable from surrounding normal tissue. This makes, in some occasions, decision making during surgery a very difficult process. During IGS preoperative imaging data is used in conjunction with images from the operative field to improve the localization and targeting of pathologies, as well as monitor and control treatments. Several advanced imaging technologies are used for IGS such as magnetic resonance imaging (MRI), computed tomography (CT), and even positron emission tomography (PET), which replace or complement direct visualization. The combination of tracking technologies for recording the position of the patient and the surgical instruments with preoperative and intraoperative images provides a comprehensive assistance tool for guiding any MIS intervention. Image-guided procedures are substantially less invasive than traditional surgery. Image-guided technology allows for more precise and accurate procedures and surgeons can decide the best approach to address a specific disease before the intervention, which may reduce the operating times as well as the number of surgical ports needed.

In general, there are some common steps followed to carry out an image-guided surgical intervention [1,2]. Initially, the patient undergoes diagnostic imaging, in most cases CT or MRI. These images are then converted and processed into a 3D model of the patient's anatomy. This information is subsequently used for preoperative surgical planning and/or intraoperative surgical decision making. During the operation, the virtual model and the surgical planning are used as a guide for navigating into the patient anatomy. During this process, the surgical instruments are tracked and mapped with respect to the virtual model to increase the accuracy during the procedure and minimize damage to normal tissues. This 3D navigation helps a surgeon to better visualize and understand the internal anatomy of the patient during each surgical step.

2.1. Components of Image-Guided Surgery

IGS integrates three major technologies: imaging, tracking, registration and visualization technologies. Each of these components will be described in more detail below.

2.1.1. Image Acquisition and Rendering

The fundamental basis of IGS is diagnostic imaging, and its progress primarily depends on technological advances in this field. No unique imaging system is exclusively used for diagnostic imaging, many different imaging modalities have been used for IGS, including ultrasound (US), MR and X-Ray imaging. All diagnostic imaging modalities have been used to guide procedures with or without some modification or adjustment. However, most image-guided navigation systems used CT or MRI systems. This is because they can provide a good quality 3D map of the anatomy, especially in the case of CT imaging. While most image-guided navigation systems are based on preoperative imaging, there is an increasing interest in using intraoperative imaging for navigation [3].

Once diagnostic imaging data of the patient has been recorded, this information needs to be processed. The goal of medical image processing is to extract quantitative information from the diagnostic images to better diagnose, localize, monitor, and treat surgical pathologies. Currently there are a large number of software tools to delineate, reconstruct and visualize patient organs and pathologies in 3D models obtained from medical imaging before surgery such as Myrian® from Intrasure, Ziostation® from Ziosoft, Synapse® Vincent from Fujinon, Iqqa® Liver from Edda Technology, Scout® Liver from Pathfinder, among others.

One of the main steps in image processing is the image segmentation. This is defined as structuring an image into different regions that are identified by signal intensities, textures, lines, or shapes. The resulting virtual model is defined by the different relevant anatomical structures that will take part during the surgical intervention [3]. Medical image segmentation is a challenging process. In diagnostic images not all the anatomical structures of interest are homogeneous and clearly separable from the surroundings. In some cases their grayscale value is not constant, and strong edges may not be present around borders. Additionally, image segmentation algorithms may not work well in the presence of poor image contrast, significant noise, and unclear anatomical boundaries. For this reason, in certain cases it is needed the intervention of an expert human operator to guide the process, which could be tedious and prone to error. Image segmentation is a fundamental step to support the surgical

treatment of tumors or in case some critical anatomical structures should be avoided during the surgical intervention.

2.1.2. Tracking Technologies

In IGS it is crucial to record the 3D position and orientation of both the patient and the surgical instruments during the intervention. These positions will be mapped later on with the 3D model obtained from preoperative imaging (registration process), to precisely visualize the instrument motion with respect to the surrounding anatomical structures. Surgical navigation systems provide surgeons with a better visualization of the anatomical structures inside the body in relation to the actual position of surgical instruments, minimizing damage of surrounding health tissues.

Currently there are different tracking technologies that are commonly used for IGS such as optical videometric (Figure 1), optical active and passive infrared, and electromagnetic [4]. Among them, optical tracking systems are the most used. They are generally highly spatially accurate (more precise than 1 mm), but suffer from the line-of-sight restrictions between the tracking device and the object to be tracked and have some limitations to track flexible instruments. Electromagnetic tracking systems do not have this line-of-sight constraint and are capable of tracking flexible objects inside the body such as catheters and the instrument tip [5].

2.1.3. Registration

Registration is another essential component for IGS; with this process the real patient and the image-based model (virtual model) are co-registered in the same reference frame. The simplest registration method is to manually match a paired-point landmark, such as the umbilicus or a nipple, between the actual organ and the overlaying image [6]. In the most common clinical scenario, radiopaque markers are attached on the patient's skin to be registered in the preoperative CT or MRI studies. Although this method is useful when superimposed on skin or bone, it is not sufficient for complex soft intraabdominal organs (non-rigid registration).

Figure 1. Videometric tracker with pattern-marked markers (Claron Technology Inc., Toronto, ON, Canada).

Registration can be broadly classified into two types: rigid registration or non-rigid registration [3]. Image registration is rigid when images are assumed to be solid and only need rotation and/or translation to be matched with each other. In commercial IGS, only rigid registration is used [4]. However, most of the anatomical structures presented in MIS are not rigid, and therefore deformations of these structures during surgery require the application of non-rigid registration algorithms, updating the anatomical changes in the intraoperative images [7,8]. Imaging data acquired by US and intraoperative CT have been specially utilized in cases requiring renewed real-time data for intraoperative deformation [9,10].

2.1.4. Visualization

The visualization techniques used to display the results during IGS can be categorized into three main types: projected images, additional monitor or transparent monitor [11,12]. The first method consists of projecting the virtual model directly onto the patient or the target organ [6]. However, in this visualization method the projector light beam may be interrupted by the surgical staff or equipment. Moreover, image deformations can occur when the images are projected onto irregular surfaces. The second method, which is the most used, makes use of an additional monitor to display the virtual model and additional information, in which the typical visualization is a four-quadrant presentation that usually consists of three orthogonal 2D images and a 3D rendering. The third method uses a transparent monitor or plate between the target organ and the surgeon's line of vision. In this case, the virtual model is superimposed on the actual real view through the transparent surface [13]. Additionally, there is a hybrid solution, which is the use of a video head-mounted display. In this case, the images from the IGS are displayed on a small video monitor mounted in front of one or both eyes using a head-mounted video camera.

2.2. Surgical Planning Systems

Surgical planning systems (SPS) use the 3D virtual models of a patient to develop a treatment plan and predefine the surgical steps. The 3D models of the patients are usually obtained from their CT or MRI preoperative imaging. These planning systems allow surgeons to interact with the virtual model of the patient, so that they can understand more in depth his/her anatomy and define the best operative strategy. SPS are excellent tools for assessing the patient's pathology and for preoperative decision-making (Figure 2). Preoperative surgical planning may improve the efficiency of MIS procedures thanks to better learning of patient anatomy and real preoperative training [14]. Therefore, using SPS surgeons can establish an improved diagnosis and a better planning of the best-suited therapy for each surgical case [15]. However, apart from all these positive implications, one limitation of these systems is the surgeon's learning curve.

Some of the features that typically include SPS are semi-automated or automated segmentation of relevant anatomical structures, identification of the lesion margins, accurate 3D model generation from the segmented data, selective visualization and transparency transforms [15,16]. These systems are particularly important for procedures where surgeons will be working close to nerves or vulnerable anatomical structures that could lead to

significant consequences during surgery. The next step will be to transfer the previous surgical planning to the patient by means of a surgical navigation system.

Figure 2. Example of a surgical planning system for intraabdominal surgery.

2.3. Surgical Navigation Systems

Surgical navigation systems (SNS), in which patient's preoperative information is used during the surgical intervention as a surgical decision-making tool, has been clinically applied in many fields to improve the safety, accuracy, and efficiency of surgeries. In MIS, due to surgeon has less visual and tactile perception than in open surgery, image assistance may be increasingly helpful for 3D understanding of the surgical target. The main aim of SNS is to specifically target an anatomical structure during surgery in safer and less invasive ways. Commercial based SNS are most widely used in neurosurgery [17], otolaryngology [18], and orthopedics [19], in which the target organs are assumed to be rigid and to have a constant spatial relationship to anatomical landmarks [20,21]. In more recent works, image-guided navigation has been extended to soft tissue applications like the liver and other abdominal organs [22,23]. However, the use of these systems in abdominal surgery is still a challenging task.

The basic setup of a SNS consists of a preoperative image data, a tracking system, a computer platform with screen, and the respective navigation software [4]. Navigation in general uses preoperative image data for example from CT or MRI images, which are used for navigation in the OR (image acquisition). Before surgery, surgical strategy, steps, paths

for the surgical instruments, and objects and areas of interest may be planned using a virtual model obtained from the preoperative images (planning). During surgery, the preoperative image data need to be matched to the current patient position by means of the tracking systems (registration). If required, the surgeon may obtain additional images during the surgery and register and include them in the running navigation.

2.3.1. Augmented Reality

The use of SNS allows surgeons to see patient's anatomical structures obtained from preoperative imaging or a prior surgical planning. However, when this information is displayed on an independent monitor, a distance between this visual information and the actual patient surgical field is created. In order to eliminate this gap, augmented reality (AR) applied to the surgical navigation is developed. Navigation surgery using AR consists in superimposing the preoperative 3D patient modeling onto the real intraoperative view of the patient [14,24], thus augmenting the real view with virtual information. AR has the potential to enhance the understanding of the pathological and surrounding anatomy during surgery by means of projecting the 3D model of the interested region. From the patient's medical images such as US, CT or MRI, AR techniques increase the surgeon's intraoperative vision by providing a virtual transparency of the patient [14]. Fine definition of dissection planes, resection margins and avoidance of injury to invisible structures are substantial applications of AR in abdominal surgery [9,25].

AR is based on two major processes: 3D modeling and visualization of anatomical or pathological structures appearing in the medical image, and the registration of this visualization onto the real patient [14]. The preoperative reconstructed images are registered with anatomic landmarks or artificial markers on the patient and then these images are tracked with regard to the patient's position, intraoperative images, as well as instruments and camera movements. Best preoperative imaging modalities are usually offered by CT and MRI, but one of the main constraints is that surgical anatomy changes drastically during surgery. Therefore, one of the most challenging aspects of AR applied to surgery is to register and merge preoperative and intraoperative images, where tracking devices are the principal protagonists in order to relate these two concepts [26]. Tracking devices link spatial information from imaging modalities, anatomical landmarks, instruments, by representing these in one common coordinate system and establishing a simple registration [26,27]. Among intraoperative imaging, US has been the most widely used image acquisition.

Surgical navigation based on AR could be defined as the next step in IGS. However, this imaging technique remains currently limited by the registration of organs deformation during surgery, the lack of studies to prove its usefulness, and the portability and cost of the required equipment [11]. The use of AR navigations systems has been extensively used in neurosurgery, otolaryngology, orthopedics, and maxillofacial surgery [21]. These surgeries allow for precise registration thanks to rigid organs and bone structures. In the case of abdominal surgery the use of AR is more challenging. One of the main problems is the need to provide a real-time updating of the changes that occur in intraabdominal structures caused by breathing, heartbeat, patient movement and interactions by the surgeons. In order to deal with these problems, soft tissue navigation methods are being developed.

Marescaux et al. [28] reported the first use of an AR-assisted intervention for adrenalectomy without a tracking system for the laparoscope. The virtual model was obtained

from a CT scan of the patient. Then, segmentation of the intraabdominal organs and 3D reconstruction of the lesion were performed. During surgery, an operator adapted manually the virtual model to the real laparoscopic images by using 7 different visible landmarks on the skin (right costal margin and 3 trocar sites) and inside the abdomen (inferior vena cava and 2 laparoscopic tools). These AR images were displayed on an independent monitor.

An intraoperative navigation system, which incorporated a port placement planning, using overlay intraperitoneal images on the patient's abdominal wall was developed by Sugimoto et al. [6]. Raw data of the preoperative patient information obtained via multiple detector computed tomography (MDCT) were used to volume rendering using OsiriX (OsiriX Foundation, Geneva, Switzerland). In order to simultaneously display the target organ and blood vessels, they injected carbon dioxide into the gastrointestinal tract and pancreatobiliary duct, and at the same time administering a rapid intravenous injection of contrast agent, then scanning, enabling the simultaneous display of the gastrointestinal tract and pancreatobiliary duct with associated blood vessels. For registration, the 3D model was set to reproduce the patient body surface, and the positional coordinates of the umbilicus, left and right nipples, and the inguinal region were fixed as physiological markers on the body surface. This registration process was non-invasive and markerless, and was completed within 5 min. They used the navigation system during seven surgeries, including three cholecystectomies, two gastrectomies and two colectomies. During surgery, 3D volume-rendering reconstructions of the gastrointestinal tract, blood vessels and soft tissue were projected on the patient's abdomen, and therefore unexpected organ injury could be avoided when the port was inserted. In laparoscopic biliary surgery, the displayed virtual cholangiography with surrounding vessel anatomy on the abdominal wall reduced the number of ports during surgery.

A real-time AR navigation system to be used in an open MRI operating theater was presented by Tsutsumi et al. [29]. The system was used during a laparoscopic cholecystectomy in three patients and during a laparoscopic ventral hernia repair in two patients. The operating theater was equipped with a 0.4-T open MRI, an optical tracking system and MR-compatible equipment such as a surgical bed, surgical lights, a respirator, a display monitor, and vital monitoring systems. To perform the laparoscopic interventions they used MR-incompatible surgical instruments, but out of the 5G restriction area as much as possible. For each patient, they place six to nine skin-affixed MRI-visible markers on the patient abdomen as well as the surgical ports. Then, an initial MRI scan was performed under the pneumoperitoneum, so that they can obtain the 3D model of the anatomical structures with the possible deformations caused by the pneumoperitoneum. Registration between the patient and the MRI images was performed by recording the space location of the skin-affixed markers on the patient using a handle probe registered by the optical tracker. Then, to the position of the laparoscope was also recorded, so that the virtual model was updated in real time with regard to the laparoscope's movement. The navigation frame rate was 8 frames per min. Laparoscopic cholecystectomy was successfully performed in three patients and laparoscopic ventral hernia repair in two patients. During the operations, the laparoscopic monitor clearly showed the AR models of the intraperitoneal structures, such as the common bile ducts and the urinary bladder (Figure 3), as well as the proper positions of the prosthesis.

Simpfendorfer et al. [30] developed an AR system that could fuse 3D models from transrectal US (TRUS) with a real laparoscopic video during radical prostatectomy. For registration of both image modalities (3D-2D), the system used custom-developed needles

with colored heads that were inserted into the prostate using conventional laparoscopic instruments. Once the navigation aids were inserted, the 3D TRUS data was acquired. These navigation aids were segmented in the 3D model as well as in the 2D video images recorded from the laparoscope. By means of this registration the system was able to compensate the organ and/or camera movements. The virtual model was superimposed on the laparoscopic video stream defining the dissection borders for the prostate, the nerves and vessels. In order to avoid the risk of spreading tumor cells, the navigation aids were removed with the prostate inside the specimen bag. The initial test of the navigation system in an in vivo human patient was successfully performed and with no complications [30]. The setup of the navigation system took approximately 12 minutes in total, including the insertion of the navigation aids, the intraoperative US image acquisition, and the creation of the models. This AR method has been also used in a partial nephrectomy [9].

Figure 3. View of the laparoscopic monitor with overlaid polygon of the urinary bladder (Courtesy of Prof. M. Hashizume, Department of Advanced Medical Initiatives, Kyushu University, Fukuoka, Japan).

Soler et al. proposed an interactive AR method for liver resection [14]. In this case, the 3D model of the patient was adapted manually to the real model, modifying its position, scale and orientation so that visible landmarks coincided both on the 3D model and the real view of the patient. Therefore, a continuous interaction of the surgeon to update the 3D model with regard to possible intraoperative alterations was needed. Besides, this system provided resection tools for virtually resecting the 3D model during the surgical intervention. This system used CT imaging data to carry out the three steps that form the entire process: 3D patient modeling, preoperative patient visualization and virtual surgical planning and intraoperative AR assistance. For the 3D patient modeling they proposed an automatic method based on hierarchical segmentation of visible organs, from the easiest to the most complex one, using the software VR-Anat©IRCAD 2011. This interactive AR system has been applied on 40 surgical oncological procedures for liver, adrenal gland, pancreas, and

parathyroid tumor resection. However, more quantitative information is needed to validate its efficiency during surgical interventions.

An AR navigation system for laparoscopic splenectomy based on preoperative MDCT was proposed by Leiri et al. [31]. For the intervention they previously segmented some important anatomical structures in the patient's 3D model such as the spleen, accessory spleen, vascular structures and pancreas, and a color-code was defined for each of them. For the registration process, five multimodality markers were placed on the patient's body, and then the MDCT scan was obtained. After scanning, the artificial markers on the patient were registered with regard to the volume image by means of an optical tracking system (Polaris, Northern Digital Inc., Ontario, Canada). After pneumoperitoneum and insertion of the scope, the registration between the spleen surface and the 3D volume was adjusted. To record the movements of the laparoscopic camera during the intervention, and therefore update the overlay images, visible infrared markers were placed on it. The overlay images were updated with about 10 fps. However, this AR navigation system does not take into account respiratory motion, pneumoperitoneum, or organ deformation. The system was used during six cases of laparoscopic splenectomy in children and all the interventions were carried out successfully. None of the cases required conversion to open surgery. During surgery, the splenic artery, splenic vein, and pancreas were fused onto laparoscopic images.

2.4. Fluorescence-Guided Surgery

Another technique for IGS is the fluorescence-guided surgery (FGS), which is an imaging technique that enables to detect anatomical structures that are fluorescently labeled during surgery. This technique allows surgeons to visualize some intraabdominal structures that are not visible with a conventional laparoscope under white light, providing an additional diagnosis tool during the intervention. FGS has the potential to improve cancer surgery outcomes, minimize the time under anesthesia and reduce health-care costs by means of its improved contrast and depth of tissue penetration compared to visible light [32]. There are different fluorescent contrast agents described in the scientific literature that can be used for near-infrared fluorescence (NIRF) imaging as a tool for photodynamic diagnostic (PDD) during MIS such as indocyanine green (ICG), fluorescein or 5-aminolevulinic acid (5-ALA) [33].

Fluorescence imaging can support the diagnosis in surgical procedures such as laparoscopic hepatectomy. This procedure has some limitations compared to open hepatectomy such as the limited possibility to visualize and palpate liver surfaces that may lead to miss some subcapsular lesions during surgery. Kudo et al. [34] used this diagnostic technique in 17 patients who underwent laparoscopic hepatectomy. To this end, a dose of 0.5 mg/kg of ICG was administered intravenously within the 2 weeks prior to surgery. ICG is a fluorescent tricarboyanine dye that absorbs near infrared light and subsequently emits light at slightly longer wavelengths. Since ICG is retained in cancerous tissues and/or non-cancerous compressed liver parenchyma around tumors, it was used during surgery as a fluorescence source. The laparoscopic fluorescence imaging system used consisted of a commercial camera (Olympus Medical Systems, Tokyo, Japan) and a cutoff filter on the camera head. Additionally, an intraoperative ultrasonography with a flexible laparoscopic probe (BK Medical, Herlev, Denmark, or Hitachi-Aloka Medical, Tokyo, Japan) was also

used to screen the whole liver. Results reported that using fluorescence imaging they were able to identify 12 hepatocellular carcinomas of the 16 cases identified (75%) and 11 liver metastases of the 16 cases identified (69%). In a study with 6 pigs, the ICG fluorescent agent was also used to detect the ischemic areas in a laparoscopic mesenteric ischemia model [35]. They injected intravenously a dose of 0.5 mg/kg 15 min after ischemia of a small bowel loop. The ICG fluorescence signal was detected using the D-Light-P laparoscope imaging system (Karl Storz GmbH & Co. KG, Tuttlingen, Germany).

Mohsen et al. [36] reported the first use in humans of fluorescein to improve visualization of biliary topography during laparoscopic cholecystectomy. This technique took advantage of the fact that the liver excretes fluorescein and ultraviolet A (UVA) excites fluorescein causing it to emit green light. A custom-made UVA source of light was used to induce fluorescence of bile. This device had an external rod with 11 mm of diameter so that it could be inserted in a 12 mm surgical port. The technique was applied to 5 patients who had symptomatic gallstones and who underwent a laparoscopic cholecystectomy. After induction of pneumoperitoneum, fluorescein sodium at 7.5 mg/kg was injected intravenously. Then, the UVA lighting device was introduced through the epigastric port and the white light from the laparoscope was reduced. In all cases the bile ducts started to show fluorescence under UVA light within 4 to 5 minutes after fluorescein injection. During the operation, the UVA light was used in three main occasions: for an initial visualization, before clipping the cystic duct and at the end, to detect possible leakage of fluorescent bile. No leakage was reported at the end of the operation. This technique allowed better and earlier real-time visualization of biliary anatomy than conventional white light. This method could be a complementary imaging technique of intraoperative cholangiography or intraoperative US. Schols et al. [37] also obtained a successful fluorescence delineation of both the cystic duct and artery using both fluorophores intravenous ICG and CW800-CA, and a commercially available laparoscopic fluorescence imaging system (Karl Storz GmbH & Co. KG). They tested the technique during a laparoscopic cholecystectomy performed in six pigs.

The use of fluorescence imaging techniques has also applied to detection of peritoneal metastasis in human colorectal cancer [38]. In this study 5-ALA was used as a fluorescent contrast agent. In cancer cells, 5-ALA causes the increase in activity of porphobilinogen deaminase and the decrease in activity of ferrochelatase, which leads to intracellular accumulation of protoporphyrin IX (PpIX). PpIX emits red fluorescence with a blue-violet light excitation (380-430 nm). This technique was tested in twelve patients with colorectal cancer. For these interventions 5-ALA hydrochloride dissolved in 20 ml of 50% glucose solution was orally administered 3 h before surgery at a dose of 15-20 mg/kg, ≤ 1 g per patient. At the beginning of the intervention, the abdominal cavity was observed in white light image as well as fluorescence image under excitation with blue-violet light and using a long pass filter on the laparoscopic camera. Peritoneal dissemination was observed in 8 patients with conventional white light observation, which were also detected with fluorescence image. A small, flat lesion was only detected using fluorescence imaging in one patient. This imaging technique has been also used as PDD in neurosurgery and urology [39, 40].

The use of infrared fluorescence imaging as PDD may help to achieve maximal nephron preservation during partial nephrectomy, and therefore avoid possible complications associated with renal insufficiency. In a study with 77 patients who underwent a laparoscopic partial nephrectomy, orally administered 5-ALA was used for intraoperative PDD of tumor type and resection margins [41]. As imaging systems they used the D-Light-P laparoscope

(Karl Storz GmbH & Co. KG). Results showed that PDD using 5-ALA was highly sensitive detecting renal cell carcinoma in dissected tumors. This diagnostic technique was able to predict the type of the lesion with an accuracy of 94% and with a positive predictive value of 98%. In another study, 2 patients underwent a laparoscopic partial nephrectomy and 17 patients a robot-assisted partial nephrectomy using ICG for PDD [42]. Before surgery, patients received intravenous injections of ICG, which was diluted to a 2.5mg/ml solution and the total doses ranged from 5mg to 25 mg until obtaining the optimal fluorescence. The intraoperative ICG fluorescence signal was visualized using the Endoscopic SPY® Imaging System (Novadaq Inc., Mississauga, Ontario, Canada). Final results reported that 13 patients had malignant lesions, where the tumor margin demarcation was most apparent with NIRF imaging. Specifically, malignant renal tumors were visualized as hypofluorescent compared with the surrounding normal renal parenchyma.

Recently, Hockenberry et al. [43] described a novel use of NIRF imaging without ICG or other injectable contrast agents to identify otherwise obscured intraluminal areas of interest during robotic-assisted laparoscopic (RAL) surgery marked by the white light of endoscopic instruments. They used the NIRF imaging system provided by the da Vinci® Surgical System (Intuitive Surgical, Inc., Sunnyvale, CA) by means of the FireFly® integrated system (Novadaq®; Mississauga, Ontario, CA). They applied this imaging technique in five patients during different urologic RAL interventions. Using this NIRF imaging, intraoperative ureteroscopy was used to identify the extent of a ureteral stricture in a patient undergoing RAL partial ureterectomy. Cystoscopy was used to identify bladder diverticula and tumor locations in three patients undergoing RAL partial cystectomy with or without diverticulectomy and the ureteral orifice in another patient undergoing RAL nephroureterectomy. In particular, during the RAL partial ureterectomy, by filtering light wavelengths below near-infrared and accentuating the near-infrared spectrum, the intraluminal white light of the ureteroscope appears green while the surrounding structures remain visible for the laparoscopic camera, which allowed surgeons to easily identify the ureteral stricture.

3. ROBOT-ASSISTED INTERVENTIONS

Compared with traditional laparoscopic surgery, robotic-assisted interventions offer advantages such as higher range of motion, 3D visualization, and scaling of movements [44]. The first robotic-assisted surgeries on humans were conducted at the beginning of 1985 using the Programmable Universal Machine for Assembly (PUMA®) model 200 developed by Unimation Company to perform CT-guided intracranial neurological biopsies. The PUMA® 200 is an industrial servo-controlled robotic arm with six degrees of freedom (DOF) that was adapted for stereotactic surgery [45,46]. Robot-assisted surgery is becoming the gold standard for urological surgeries including prostatectomy, and it seems that gynecology is the next main focus. With the continuous advances in surgical techniques and surgical robotics, it is expected that in the future all surgical treatments can be performed by endoscopic procedures or by robot-assisted surgery. However, at the moment, a robotic surgical operation is too far to be performed entirely without human control. Surgical robots are generally used for specific surgical tasks such as supporting and improving the intracorporeal suture, holding the

laparoscopic camera or taking a biopsy. Although, there are some more complex robotic platforms, as the da Vinci® Surgical System, that can be used as a support to complete the entire surgical procedure.

Despite their wide benefits there are some problems that remain to be solved in robotic surgery such as the price of surgical robots and their maintenance, the size, the lack of training for surgeons, and the few available studies that confirm the improved performance and outcomes of robotic-assisted surgical procedures.

3.1. Surgical Robots for MIS

In this section, some of the most popular robotic surgical systems for MIS, which are commercially available or in their last stages of development prior commercialization, are described.

3.1.1. Automated Endoscopic System for Optimal Positioning (AESOP®)

The earliest commercial system for robotic laparoscopic surgery which was accepted by the surgical community was the Automated Endoscopic System for Optimal Positioning (AESOP®). This system was developed by Computer Motion (Santa Barbara, CA, USA), a company that was founded with grants from National Aeronautics and Space Administration (NASA) and the National Science Foundation (NSF). The AESOP® system was able to control automatically the motion of a laparoscopic camera attached to its robotic arm. This support system allows for more precise and consistent movements of the laparoscopic camera, providing surgeons with a steadier view and filling the needs for holding the camera by a surgical staff during the entire procedure. Additionally, the AESOP® system controls the motion of the camera by means of surgeon's commands transmitted by either foot pedals or voice [47]. This system was cleared by the Food and Drug Administration (FDA) in 1994 to assist surgeons in MIS.

The AESOP® camera holder has been used during routine gynecological endoscopic surgical procedures [48]. The previous study reported that the voice-controlled AESOP® works more efficiently and faster than the hand or foot control. This device has been also used during laparoscopic radical prostatectomy [49] and laparoscopic cholecystectomy, among others minimally invasive surgical procedures.

3.1.2. ZEUS® Surgical System

After the initial success with AESOP®, Computer Motion decided to develop an entire robotic surgical system with surgical manipulators based on three AESOP® arms, the ZEUS® Surgical System. Two arms were designed to host the surgical instruments and one for the laparoscopic camera. The ZEUS® Surgical System is a master-slave system with remote manipulators controlled by means of a console. The surgeon seated at the console should wear polarized glasses to perceive the 3D image from the flat monitor. In 2001 the FDA cleared Computer Motion's ZEUS® Robotic Surgical System for use in abdominal operations [50]. This surgical system provided tremor filtering and scaling function. In 2003 Computer Motion was acquired by Intuitive Surgical, discontinuing the commercialization of both AESOP® and ZEUS® robotic systems.

This surgical platform was originally designed for minimally invasive procedures such as beating heart, coronary artery bypass grafting and mitral valve repairs [51]. ZEUS® has been used to harvest internal mammary arteries [52] and to perform in 1998 the world's first robotically-assisted minimally invasive coronary artery bypass grafting at the University Hospital Munich-Grosshadern in Germany [53]. ZEUS® is also well-known for the "Lindbergh" surgery in 2001 where a surgeon in New York, USA, performed a laparoscopic cholecystectomy in Strasbourg, France, demonstrating for the first time the feasibility of telepresence surgery [50,54].

3.1.3. The da Vinci® Surgical System

The emergence of laparoscopic surgery, combined with the interest of the US Army to operate on severely wounded soldiers directly in the battlefield or in the route to a field hospital led the NASA and the Stanford Research Institute (SRI) to focus their research programs on telesurgery [55]. This initiative was significantly supported by the Defense Advanced Research Projects Agency (DARPA). Their efforts were eventually very fruitful and the research produced a robotic endoscopic surgical system. However, limitations in telecommunication and funding prevented its implementation in the battlefield. Instead, the robotic platform was adapted for civilian and commercialized by Intuitive Surgical Incorporation (Sunnyvale, CA, USA) as the da Vinci® Surgical System [56].

The da Vinci® Surgical System was first launched in 1999. The main purpose of this robotic surgical system has been to provide a reliable, intuitive, surgical platform that brings the benefits of MIS to the patient while the surgeon is performing the procedure with similar conditions to open surgery such as higher dexterity, better ergonomic conditions and 3D visualization. Initially, the ability of this surgical platform to manipulate delicate tissues was applied to cardiac surgery. Subsequently, the benefits of this surgical robotic platform were extended to other surgical disciplines.

Figure 4. The da Vinci® Si System in an OR with the double console (©2014 Intuitive Surgical, Inc.).

Nowadays, the da Vinci® Surgical System is the only commercially available master-slave robotic system. At the end of 2012, there were more than 2,500 da Vinci® Surgical Systems installed in over 2,000 hospitals worldwide [56]. Therefore, at present this surgical robotic system is the most commonly used for performing minimally invasive laparoscopic surgery in humans (Figure 4).

One of the main features of this surgical system is its EndoWrist® surgical instruments (Intuitive Surgical, Inc.; Sunnyvale, CA, USA) that translate the movements of the instrument handle to the remote tip in an intuitive manner, avoiding the fulcrum effect. The end effector of these instruments mimic human hand motion by a mechanical articulation, providing surgeons with additional three DOF (seven in total) and about 90° of articulation in the wrist. These features provide surgeons with a full range of motion during the performance of minimally invasive procedures. However, not all the provided instruments are wristed such as the Harmonic® ACE and the single-site instruments. Additionally, the da Vinci® Surgical System is equipped with tremor filtering, scaling function, and alignment of the eyes and hands with the provided image of the instruments tip. The surgical image is displayed in real time through a high-quality 3D endoscope into the stereo viewer. Besides, this stereo viewer allows for additional visual information such as CT or US images.

There have been four commercial models of the da Vinci Surgical System: the da Vinci® Standard System, the da Vinci® S System (released in 2006), the da Vinci® Si Surgical System (released in 2009), and the most current version, the da Vinci® Xi System (released in 2014). The da Vinci® Standard System has been discontinued from sale and is no longer supported by Intuitive Surgical. The second version, the da Vinci® S Surgical System, was designed to facilitate surgical setup through a slimmer arm design and the addition of a fourth robotic arm. The da Vinci® Si version was equipped with a 3D full high-definition vision system, a second console for training, the availability to perform single-site surgery, and the integration of laser technology to allow for fluorescent imaging [56]. One of the most remarkable advances of the latest version, the da Vinci® Xi Surgical System, is that it allows for multi-quadrant surgery that can be performed without repositioning the system. Additionally, this version provides smaller and thinner arms as well as the ability to attach the endoscope to any arm. At the moment, Intuitive Surgical remains the market leader for robotic MIS by holding the license of more than 1,000 patents that cover the fundamental aspects of the da Vinci® Surgical System's technology such as the surgical console, the vision system and the wristed instruments. This hampers the development of new robotic surgical systems.

This surgical platform has been successfully used in a wide range of abdominal [57] and thoracic procedures [58]. In addition, it has been applied to other emerging procedures such as single-site surgery [59, 60] and Natural Orifice Transluminal Endoscopic Surgery (NOTES) [61,62] in an attempt to further reduce the invasiveness of surgery. Although this is a system for telesurgery and all robotic arms are controlled remotely from the surgical console, its installation, removal, and exchange of the camera as well as the instruments should be performed by a bedside assistant. Besides, for some interventions installation of the system is time-consuming considering that for some procedures time is a critical issue. Although the latest version, the da Vinci® Xi System, seems to have improved this limitation.

3.1.4. *Amadeus® Surgical System*

Similar to the da Vinci® Surgical System, another project that is currently under development is the Amadeus® system (Titan Medical Inc., Toronto, Canada), which is a 4-armed robotic surgical platform for MIS with snakelike multiarticulating arms for improved maneuverability and obstacle avoidance [63]. As the da Vinci® Surgical System this surgical platform consists of a master-slave robotic system with a workstation that allows surgeon to control remotely the robotic surgical instruments. This workstation also provides surgeon with 3D endoscopic view of the surgical field and a set of instruments for single-site surgery. In addition, this system includes force feedback for detection of tissue-level forces, which allows surgeons to feel how hard they are pulling on tissues, sutures, or other structures, minimizing tissue damage. Currently, the company has put the Amadeus system on the back burner to focus their efforts on developing and commercializing a new robotic platform for Single-Site Surgery, the Titan's Single Port Orifice Robotic Technology (SPORT™) surgical system.

3.2. Robotic Surgery in MIS

The introduction of laparoscopic surgery came with some technical limitations including mirroring of instrument movements, limited articulation, two-dimensional (2D) visualization and poor ergonomics, which may lead to some surgical complications [64]. These technical limitations of laparoscopic surgery significantly influenced the development of robotic surgical systems as a means to improve the control of laparoscopic instruments, providing wider maneuverability in complex procedures, and improve visualization of the surgical field. Some advantages of robotic surgical systems include 3D vision, increased precision and dexterity, and ergonomic conditions for the surgeon that may lead to less muscle fatigue. However, in order to ensure the success of a robotic procedure, a variety of factors must be taken into account such as the surgical system to be used, the appropriate selection of surgical equipment as well as patient and procedural considerations.

3.2.1. *Robotic-Assisted Urological Surgery*

Robotic was first introduced in urological surgery in 1991 to conduct a transurethral resection of the prostate using the robotic system Probot® (Imperial College, London, UK), a resection device with seven DOF. For this procedure, the surgical robot was used to insert into the patient a cutting device for removing the prostatic tissue. This system possesses a transurethral ultrasonographic probe at its tip to measure the gland at the beginning of the procedure, providing an intraabdominal model of the prostate in which the surgeon can define the area to be removed. Then, the robotic system computes the trajectories of resection for the surgical tool and follows them during the intervention [65].

There are a substantial number of studies on performing complex urological procedures with robotic assistance in humans that has documented their safety, efficacy, and feasibility [66]. These studies have applied robotic-assisted surgery to several urological domains such as localized prostate cancer (radical prostatectomy), bladder cancer (radical cystectomy and urinary diversion for muscle-invasive bladder cancer), kidney surgery (nephrectomy, donor

nephrectomy, partial nephrectomy), pyelo-ureteric junction obstruction (pyeloplasty), and adrenal surgery [67].

The first successful laparoscopic radical prostatectomy was performed by Schuessler in 1991 [68]. However, due to its technical difficulty, this operation was not widely carried out until the da Vinci® surgical system appeared. The miniature tools with EndoWrist® technology offer a potential advantage over standard laparoscopic instruments in the accuracy of movements and suturing along with high-magnification 3D view. This ensures preservation of the lateral prostatic fascia, which may result in better erectile function postoperatively as compared to conventional open surgery [69,70]. RAL radical prostatectomy seems to reduce the blood loss, risk of intraoperative transfusion, and anastomotic strictures in comparison with retropubic radical prostatectomy [71]. Consequently, this new technology has spread rapidly, and in 2009 about 85 % of all radical prostatectomies in the USA were performed by assistance of the da Vinci® surgical system [67,72].

In the case of partial nephrectomy, although open approach remains the reference standard for the treatment of small renal tumors, laparoscopic partial nephrectomy is constantly evolving. However, this is a challenging approach due to its steep learning curve and technical requirements. To cope with some of these limitations, robotic technology has recently been applied to laparoscopic partial nephrectomy with the goal of providing a safe and effective alternative to laparoscopic partial nephrectomy [73]. The first robot-assisted partial nephrectomy was described by Gettman et al. [74] in 2004. Some studies suggested that RAL partial nephrectomy offers equivalent oncological control to open and laparoscopic partial nephrectomy while reporting shorter hospital stay, less intraoperative blood loss, shorter operating room time and shorter warm ischemia time [73,75,76].

3.2.2. *Robotic-Assisted Cardiac Surgery*

The application of laparoscopic techniques to cardiac surgery entails some difficulties such as the lack of dexterity using the conventional laparoscopic instrumentation that is required for delicate cardiac surgical procedures and the loss of depth perception due to the 2D vision. The application of robotic technology has overcome some of these limitations, providing new approaches to minimally invasive cardiac surgery.

In 1998 Stephenson et al. [77] reported the first robot-assisted totally endoscopic coronary anastomosis on twenty-five isolated porcine hearts placed inside a thoracic trainer, using an arterial conduit to the left anterior descending artery. The procedure was performed endoscopically using the ZEUS® Surgical System [77]. All the 25 surgeries were successfully completed and showed good probe patency. The lack of tremor and motion scaling allowed for the precise movements required to complete the endoscopic microvascular anastomosis. Loulmet et al. applied the first robotic totally endoscopic coronary artery bypass grafting in humans in 1998 [78]. This intervention was performed in 4 male patients with the indication of grafting the left internal thoracic artery to the left anterior descending coronary artery. The da Vinci® Surgical System was used to perform the surgery and the Heartport® system (Heartport, Inc, Redwood City, USA) was used for arresting the heart during the anastomosis. Carpentier et al. [79] performed the first robotic mitral valve repair using an early prototype of the da Vinci® Surgical System in 1998.

The FDA approved the da Vinci® Surgical System for mitral valve surgery in 2002 and in 2004 for use in coronary anastomosis during cardiac revascularization. Some of the most common applications of robot-assisted cardiac surgery are the mitral valve repair [80] and endoscopic coronary artery bypass grafting [81,82]. Over 1,700 robotic cardiac operations per year are currently performing in the USA and the numbers are increasing each year [83].

The CardioARM® is one of the latest surgical robots that have being introduced is in the field of cardiac surgery. CardioArm® was developed at Carnegie Mellon University (Pittsburgh, USA). This system consists of a slim snakelike manipulator designed to perform minimally invasive epicardial interventions through a subxiphoid approach. The CardioARM® was developed in an effort to provide dedicated intrapericardial therapeutic delivery with single port access. One of the main advantages of this design is the ability to preserve its previous configuration and shape in intraabdominal space during navigation or to become completely flexible if necessary [84].

3.2.3. Robotic-Assisted Thoracic Surgery

The application of MIS to thoracic surgery has been slow mainly due to some difficulties that entail this type of surgery such as the limited thoracic space, the ribs restrictions, the heartbeat and the breathing [85]. The initial application of video-assisted thoracic surgery was only as a diagnostic tool. The development of specific thoracoscopic instruments led to more complex procedures such as pulmonary lobectomy. Apart from its technical demand, thoracoscopic surgery has a steep learning curve because of the unergonomic position and two-dimensional view. In this sense, advances in robotic surgery have tried to solve some of these limitations.

Several cases have been reported in which robotic-assisted thoracoscopic surgery has been performed for the early-stages of lung cancer [86,87]. Jang HJ et al. [88] compared the results of forty cases of robot-assisted lobectomy (RAL) with forty cases of video-assisted thoracic surgery lobectomy (VAL) for lung cancer. Results showed no conversions to open thoracotomy in RAL against 2% for the VAL group. The operative time for both surgical techniques was similar, but the rate of postoperative complications in the RAL group ($n = 4$) was significantly lower than that of the VAL group ($n = 13$). Additionally, postoperative stay was significantly shorter for the RAL (6 vs 9 days). Park et al. [89] reported that the cost in the USA of video-assisted or robotic-assisted thoracic surgery for lung cancer was lower than open thoracotomy due to the longer hospital stay than this later required.

The mediastinum, especially the upper part, is a delicate and difficult anatomical area to be reached through thoracoscopy mainly because this anatomical area has large and fragile vessels and nerves. Thoracoscopic surgery has some limitations that make those maneuvers more difficult such as the 2D view of the surgical field and the lack of DOF of the surgical instruments that limit the maneuverability. The thoracoscopic thymectomy is considered a technically challenging operation that requires a long learning curve [90]. The introduction of robotic surgical system has dealt with some of the aforementioned problems, mainly the increasing in maneuverability compared to conventional thoracoscopy [85]. However, the lack of tactile feedback of most of the current robotic systems may increase the risk to damage the tumor tissue, increasing the possibility of tumor seeding.

3.2.4. Robotic-Assisted Gynecological Surgery

Since its approval for use in gynecologic surgery by the FDA in 2005, the da Vinci® Surgical System has been widely adopted by hospitals and gynecologic surgeons [91]. At the moment, it is the only commercially available robotic surgical platform for gynecologic surgery in the US. The application of robotic technology has had a strong impact in abdominal and pelvic surgery. One of the most influential results is a decrease in the number of procedures performed by laparotomy, even in the case of obesity, which leads to a reduction in blood loss, shorter hospitalization, and shorter recovery to normal activities [92,93]. Magrina et al. [92] reported a 3% of conversion rate with robotic surgery for endometrial cancer in comparison to 10% for laparoscopic patients. Robotic-assisted surgery has been extensively applied in gynecological surgery in benign gynecology as well as gynecologic oncology. Robotic-assisted surgery allows gynecologists to perform minimally invasive hysterectomies [94], myomectomies [95], and lymph node biopsies [96] without the need for large abdominal incisions.

3.3. Robotic Single-Site Surgery

Since the introduction of laparoscopy, MIS has experienced great advances and innovation, in the pursuit of the final objective to eliminate or keep invisible all scars after surgery. In this sense, laparoendoscopic single-site surgery (LESS) is now consolidated as a real alternative to conventional laparoscopic surgery, with numerous studies sustaining its feasibility and therapeutic safety [97-99]. In this new approach, articulated or prebent instruments are introduced into the abdominal cavity through specific multichannel ports or conventional low profile laparoscopic trocars, placed in close proximity through one single incision. If the surgical procedure is performed with an additional transperitoneal port, it is referred to as hybrid LESS. This way, and still lacking scientific proof, single incision offers various theoretical or potential advantages, such as better cosmetic results, lower incidence of incisional pain, and faster recovery. This surgical technique particularly contributes to excellent cosmesis results mainly because of the surgical scars are often undetectable, especially when the surgical entrance is through the umbilicus.

Apart from its benefits, LESS surgery presents some specific difficulties, which include the reduction in freedom of movement, inline vision with loss of triangulation [100], and closer proximity of instruments, leading to external and intraabdominal clashing and crossing [101], and the deficient ergonomics for the operating surgeon [102]. Clashing of instruments could be partially avoided by using prebent, articulated or instruments of different lengths. Additionally, when using flexible instruments, the size and weight of tissue that can be held are limited owing to the insufficient force transmitted through the instruments.

In an attempt to overcome these problems, new specifically designed instruments and devices are being developed. In this regard, robotic systems for LESS may improve the ability to maneuver within the abdominal cavity due to the possibility of use articulated robotic instruments and with higher number of DOF. This has led to a new kind of surgery, robotic LESS or R-LESS. R-LESS promises to overcome the limitations of laparoscopic single-site surgery by eliminating instrument clashing and reproducing conventional triangulation in a

single incision environment. However, further developments are needed in order to optimize the current robotics systems to single-site surgery.

3.3.1. *da Vinci® Surgical System*

The first application of single-site robotics in gynecology was reported by Escobar et al. using standard EndoWrist® instruments directed through a GelPort® (Applied Medical; Rancho Santa Margarita, USA) through the umbilicus [103]. Also Kaouk et al. reported the first clinical cases in humans of robotic single-site surgery for radical prostatectomy, radical nephrectomy, and dismembered pyeloplasty using the da Vinci® S Surgical System [104]. In July 2009, White et al. [105] mentioned the first clinical cases of R-LESS uretral reimplant and sacral colpopexy. The first application of R-LESS in digestive surgery was reported by Ostrowitz et al. [106]. Romanelli et al. [107] mentioned the first R-LESS cholecystectomy and Allemann et al. [108] reported the performance of a Nissen fundoplication on 18 pigs either with R-LESS or LESS.

In 2009, Intuitive Surgical Inc. released the third generation of da Vinci® Surgical System, the da Vinci® Si System, which included a wide range of specialized instruments for single-site surgery, a surgical simulator and near-infrared imaging capabilities [109]. The da Vinci® Single-Site Instrumentation kit contains material that has been specifically designed to enable robotic surgery through a single incision of 2-2.5 cm. These surgical instruments are inserted thorough curved trocars, and therefore avoiding collisions between the robotic arms. Additionally, the robotic system can switch the instruments in the right and left side on the control panel, which allows the surgeon to manipulate the instruments on the console as they were not crossed [44]. These new instruments for LESS have been tested for cholecystecmy [59], pyeloplasty [60] and nephrectomies procedures [109], amount others.

However, the flexible instruments for R-LESS provided by Intuitive Surgical are not wristed, and therefore the surgical performance is as if straight-stick conventional laparoscopy instruments were using. In addition, the flexible instrument shafts, necessary for instrument delivery through curved cannulas, limit the tolerance for load of the instruments, causing the shaft could be bent when it has excessive load.

3.3.2. *Single-Port Laparoscopy Bimanual Robot (SPRINT®)*

The SPRINT® is a master-slave teleoperated robotic platform developed for bimanual interventions by means of single access port. This system consists of two robotic arms with a maximum diameter of 18 mm and a stereoscopic camera (Karl Storz GmbH & Co. KG). This device mounts two graspers that differ in shape and size, which are controlled using a wire-driven mechanism (Figure 5). Each grasper can applied up to 5 N of force. Each robotic arm has embedded the motors and gear boxes, which provide them six DOF. The surgeon's console consists of two manipulators for each of the robotic arms, one pedal and a 3D Full-HD vision system with polarized glasses. Two Phantom Omni haptic devices (Sensable Technologies Inc., Woburn, USA) are used as manipulator, thus enabling to control all six DOF of each robotic arm. This robotic system is still in the prototype phase and still presents some mechanical constraints [110].

The initial tests of this surgical system have been carried out on an in vivo animal model. A midline laparotomy of (approximately 10 cm) was performed and the abdominal cavity was exposed by means of a fixed retractor. The robotic system was fixed to the OR table and

suspended over the incision made in the abdomen of the patient. A surgeon controlled remotely both arms of the robotic system during the performance of a small-bowel enteroenterostomy [111].

Figure 5. SPRINT® robot for single-site surgery. (a) Surgeon console with the manipulators and the 3D monitor. (b) SPINT® robot setup in the OR (Images from [111]. Reprinted with permission).

3.3.3. Plate- Spring Mechanism-Based Laparoscopic Surgery Robot (PLAS®)

The PLAS® prototype consists of two flexible arms assembled in a Y-shaped design [112]. Unlike the traditional wire- or link-driven mechanisms used to move the instrument arms [111], this device uses a novel plate-spring mechanism, which provides more than 14 N force transmission. This high force transmission allows for performing a wide range of surgical procedures through single port access. In contrast to the bulkiness of gearboxes and the weaknesses of wired systems, plate springs can deal with these limitations. The movements of both arms could achieve a total of 12 DOF. This feature could be one of the most competitive with regard to the other similar robotic systems, allowing the device to reach a wide workspace inside the abdominal cavity. This system has been only experimentally tested on in vivo animal models. During these experiments, a surgeon performed a liver dissection using PLAS®, determining that it has sufficient force transmission capability to handle the organs during surgery [112].

Nevertheless, the current version of PLAS® does not have an additional supporting structure to hold the endoscope and tool change is not possible. Therefore, several ports and forceps might be required to perform an entire procedure. In addition, this device does not provide haptic feedback from the end effectors to the user's manipulators.

3.4. Robotic Natural Orifice Transluminal Endoscopic Surgery

The concept of natural orifice transluminal endoscopic surgery, most commonly known as NOTES, constitutes a new surgical approach that combines aspects of flexible endoscopy and laparoscopy, where the ultimate goal is to ensure the absence of scars in the skin of the patient. NOTES can be performed as a hybrid procedure, in case surgeon requires laparoscopic assistance or as a pure procedure, if no accessory trocar through the patient's abdominal wall is needed.

This type of surgical approach avoids the need to make any abdominal incisions, which may correlate with fewer wound infections and a faster recovery and return to daily life. Available literature confirms the feasibility and security in the short term of a variety of transluminal procedures, including cholecystectomy, appendectomy, tubal ligation, gastrojejunostomy, nephrectomy, pancreatectomy and splenectomy [113-115]. The body's orifices are considered natural routes, and reported entrances to the abdominal cavity include transgastric, transcolonic, transvaginal and transvesical. Once the transluminal procedures are completed, the endoscope is withdrawn through the natural orifice and the incision is closed by using clips or endoscopic suturing devices.

Some of the limitations of this technique include inefficient tissue traction, inadequate triangulation of instruments, and existing risk of abdominal infections due to an incorrect disinfection or visceral closing. In NOTES, to perform the surgical procedures, surgeons have to manipulate endoscopic forceps through the flexible endoscopic channel, which in some cases it does not provide the degree of maneuverability required to perform the procedure without complications. Additionally, current endoscopes and instruments remain inadequate to perform complex surgeries by NOTES approach. NOTES itself requires the acquisition of new equipment and surgical skills for deployment in the surgery, which demands for the development of specific training programs.

To overcome the aforementioned limitations, the use of robotic technology could provide a potential solution to increase the dexterity in manipulating the endoscopic forceps in a narrow visual field and a small cavity. This leads to the concept of robotic natural orifice transluminal surgery (R-NOTES).

3.4.1. da Vinci® Surgical System

The use of the da Vinci® Surgical System for robotic-assisted NOTES has been reported in animal and cadaveric models, but not in the case of human patients. The initial experience with robotic natural orifice transluminal surgery (R-NOTES) using the da Vinci® Surgical System was reported by Haber et al. [116] for reconstructive urology. In this study, they performed 10 robotic-assisted hybrid transvaginal NOTES pyeloplasties, 10 radical and 10 partial nephrectomies in 10 in vivo porcine models. For performing these procedures, the robotic laparoscope and the first robotic arm were placed through a single umbilical incision by means of a single-port multicannula, and the second robotic arm was placed through the vagina. All the procedures were performed successfully without any open conversion or additional laparoscopic port. In a study with 3 female cadavers, two different approaches for retroperitoneal transvaginal R-NOTES nephrectomy were reported using the da Vinci® Si System in a 3-arm configuration [61]. In the first approach, the peritoneal cavity was accessed in the lithotomy position and in the prone jackknife position during the second approach. Access to the peritoneal cavity was obtained by means of a single-port device inserted through the vagina. The results showed that the first approach could not be successfully performed due to collision of the robotic arms against the legs and limited bowel retraction. During the second approach, in one of the subjects there was a rectal injury during the access and the procedures could not be completed because they could not reach the kidney with the robotic instruments due to the height of the subject. Using also a cadaveric model, Eyraud et al. [62] completed successfully a transrectal hybrid R-NOTES nephrectomy and adrenalectomy.

Demura et al. [117] analyzed the feasibility of using the da Vinci® Surgical System for a transrectal small intestinal anastomosis and closure of the rectal anterior wall incision in a porcine ex vivo model. A Tuebingen MIC trainer (Richard Wolf GmbH, Knittlingen, Germany) was used as surgical setting, in which the ex vivo small bowel segments were placed. Surgical performance using the R-NOTES approach was compared with traditional transabdominal robot-assisted surgical approach as well as using transanal endoscopic microsurgery instruments (TEM NOTES). For the R-NOTES procedure, two 8-mm robotic arms were inserted through the anterior rectal wall orifice of the box trainer and placed horizontally, and a 12-mm camera was inserted through the same orifice and placed above the two arms. The number of experiments with each approach was 12. Results showed that the mean burst pressures in the transrectal R-NOTES group and the transabdominal robotic group were significantly higher than in the TEM NOTES group. Besides, the surgical time was shorter in the R-NOTES group than in the TEM NOTES group, but longer than the transabdominal robotic group.

Although the use of the da Vinci® Surgical System provides several benefits for the surgeon such as the increase dexterity, multiple DOF and 3D vision, using this robotic system for NOTES is still technically challenging. For this reason, further refinements of this technique as well as development of new surgical instruments and devices should be done. On the other hand, novel surgical devices and prototypes focus on providing new alternatives for R-NOTES are described below.

3.4.2. Endoscopic Surgical Robot for Tele-NOTES

In 2009 Suzuki et al. [118] reported the first telesurgery experiment by performing a NOTES procedure (Tele-NOTES). In this experiment they used an endoscopic surgical robot inserted through the esophagus to perform surgeries in the upper gastric tubes and the abdominal cavity through the stomach wall. Therefore, this surgical robot was able to perform intraabdominal surgeries without any external incision on the patient. The robotic system consisted of one central camera and two robotic arms, which were controlled by means of a wire-driven mechanism. The surgeon controlled the system from a surgical console, which consisted of two haptic devices (PHANTOM Omni, SensAble Technologies Inc., MA, USA) for the manipulation of forceps (Figure 6). The robot could perform grasping, incising and clipping of soft tissue using the cooperative action of left and right robotic arms.

Figure 6. Endoscopic surgical robot for Tele-NOTES. (a) Surgical robot inside the abdominal cavity. (b) Remote operation unit to control the robotic arms (Courtesy of Prof. M. Hashizume, Department of Advanced Medical Initiatives, Kyushu University, Fukuoka, Japan).

The system has been previously used for endoscopic mucosal resection in stomach, and NOTES procedures on liver, gall bladder, small intestine and oviduct in animal models [118]. For the Tele-NOTES experiment they performed a lymph node dissection between Japan and Thailand (distance of about 3,750 km) using a human soft cadaver. The robotic system was controlled by the cooperative direction of a surgeon and an endoscopist. The surgeon was placed on the surgical console in Japan, who was in charge of manipulating the robotics arms. The endoscopist was on the patient side in Thailand controlling the endoscope.

3.4.3. *EndoSAMURAI®*

The EndoSAMURAI® (Olympus Corp., Tokyo, Japan) is a prototype platform consisting mainly of an endoscope and a control console. This endoscopic platform has two independent end effectors with five DOF, a third conventional working channel, and an ergonomic user interface [119]. The main advantage is that the console has similar actuators used in conventional laparoscopic surgery, thereby adapting to the use of the system is usually less complex and more intuitive for a laparoscopist. The two articulating working arms can be moved out of the original diameter of the scope and therefore provide more triangulation. However, this may reduce the maneuverability in tight spaces lumen such as in the oesophagus or small bowel. The system has some similar functions to a traditional endoscope such as the light source and insufflation of gas, but also standard functions for suction and the possibility of rinsing the endoscopic lens. Exchangeable instruments via the working channels of the scope allow for a variety of working functions including grasping, retracting, tissue cutting, coagulation, hemostasis, and suturing with a needle holder. In general, the system is operated by two individuals: the main surgeon placed at the workstation and the camera assistant who guides the endoscope within the abdominal cavity [120].

This device has been compared in a benchtop simulation with a conventional dual-channel endoscope during the performance of bimanual coordination tasks such as suturing and knot-tying [119]. Results showed better results for the novel device in time and accuracy. Recently, the EndoSAMURAI® has been tested in an experimental in vivo porcine model by performing a transgastric small bowel segmental resection with acceptable quality and within a reasonable time (110 min) [120].

3.4.4. *Master and Slave Transluminal Endoscopic Robot (MASTER®)*

Another robotic prototype for NOTES that is used with a conventional endoscope is the MASTER® (Nan Yang Technological University, Singapore). This consists of two small cable-driven flexible arms with nine DOF located at the tip of the endoscope. These cables have the enough size to be inserted through the channels of a conventional flexible endoscope with double channels. Moreover, this robotic platform provides a console for the manipulation of the surgical tools in a more intuitive manner. This console is adapted to the surgeon's needs allowing for a more ergonomic position during the intervention. The master controller is attached to the wrist and fingers of the operator and connected to the manipulator by electrical and wire cables [121]. The robotic arms allow for tissue manipulation, triangulation, off-axis forces and monopolar cautery. This system also requires an endoscopist as well as a robotic operator to perform a surgical intervention. However, there are some limitations that should be improved in future versions such as automation of camera control and an easier exchange of instrument.

This device has already been tested in ex vivo and in vivo animal models for endoscopic submucosal dissection. The novel device has been shown to have faster learning curve than using conventional endoscopic equipment to complete the procedure [121]. Recently, Phee et al. [122] performed the same procedure in 5 human patients with early-stage gastric neoplasia, limited to the mucosa. After markings and circumferential mucosal incision, all submucosal dissections were performed using the MASTER® system. All surgeries were successfully performed with no residual or recurrent tumors. Additionally, the MASTER® system has been used to perform wedge hepatic resection through the transgastric route on two female pigs. Results showed that the procedure using the novel device was accomplished successfully in both patients without the need for assistance using laparoscopic instruments [123].

3.4.5. Miniature Robot for NOTES

The robotic systems for NOTES based on the endoscope that use cable-driven arms are prone to generate friction during wire actuation inside the endoscopic channels. This may cause significant amount of hysteresis and ineffective force transmission, thus resulting in lack of instrument responsiveness and accuracy [124]. An alternative to this problem is to use systems that do not require cable-driven mechanism as the miniature robot for NOTES developed at the University of Nebraska-Lincoln (Lincoln, USA) [125]. This device, with tubular shape, consists of two arms connected to a central body by a rotational joint. This miniature robot has two remotely controlled actuators with six DOF, stereovision and ultra bright LED lighting. Both cautery and forceps are the end-effectors provided by this device. The actuators are remotely controlled by the surgeon using an external console, which consists of two joysticks for controlling the robotic arms and a TFT color LCD monitor located between the two joysticks to display the video from the endoscopic camera.

In order to be introduced into the peritoneal cavity through the esophagus by means of a standard therapeutic endoscope, this system acquires initially a linear configuration. Once the system is inside the abdominal cavity it is restructured again into three parts using an external magnetic handle that interacts with magnets housed in the robot body. The exterior magnet handle can be moved along the outer surface of the abdomen for repositioning the robot throughout the procedure. This robotic system has been tested for an abdominal exploration, a bowel manipulation, and a cholecystectomy in three ex vivo porcine models [125]. Results of this study reported that the robot has the sufficient flexibility for transgastric insertion while providing a stable platform for tissue manipulation and visualization of the surgical field. Besides, the robotic arms were able to provide the sufficient force for tissue retraction and dissection during the procedures. However, this system experienced some problems during the execution of some of these surgical procedures. In one case, the robotic device did not have the enough magnetic coupling for attaching the robot to the interior abdominal wall and, in another procedure, there was a mechanical failure in one of its shoulder joints.

3.5. Image-Guided Robotic Surgery

The principal disadvantage of the conventional endoscopic technique is that it is difficult to maintain precise control of the endoscopic instruments because of limited range of

movements of the surgical instruments, heartbeat, breathing movements, instable visualization of the operative field, and haptic input. These limitations make difficult to perform some procedures that need for high precise movements such as tumor resection or cardiac surgery. In this sense, robotic technology along with image-guided techniques is a feasible solution to cope with these surgical requirements. Needles, slender probes or other instruments can be inserted into the body using real-time feedback of different imaging modalities, such as CT, MRI, US and fluoroscopy [27]. In this sense, we will focus our attention on robotic systems that are placed in imaging devices using them during the course of the intervention.

3.5.1. Tumor Therapy

One of the most popular robotic platform for tumor ablation is the CyberKnife® system (Accuray, Inc., Sunnyvale, USA), which was the first image-guided robotic system for noninvasive radiation procedures. This robotic system was developed in 1987 as an interventional radiological robot and received the FDA approval in 2001. It consists of a large robotic arm that can quickly and accurately deliver targeted radiation with converged beams from multiple angles, reducing radiation exposure to surrounding tissue [126]. Before the intervention, a CT scan of the patient is imported into the treatment planning system. Then, the robotic manipulator automatically follows a fixed preplanned path to target the lesion, but this path can be modified automatically along the treatment on the basis of possible patient displacement. Because the patient is in continuous motion and the interior of the human body is an unstable scenario, CyberKnife® updates its spatial registration of the patient prior to each dose using an X-ray imaging system and a respiratory tracking system to track and anticipate respiratory motion [127,128]. The X-ray images are used during the treatment to compute the changes in position of the patient using the CT images as baseline, and therefore making continuous adjustments for movement. This image-guided robotic system has been used for radiotherapy of brain tumors, lesions of the spine, lung, pancreas, liver, and prostate [126].

In 2012 The Indian Perfint Healthcare Corporation (Chennai, India) released the MAXIO® system, which is an integrated planning, navigation and robotic targeting system for CT-guided tumor ablation. The use of this platform can be divided into four phases: Image registration, planning, treatment and verification. Once the CT images have been obtained, the next step is the image segmentation using a semi-automatic segmentation method. After the image segmentation has been performed and the tumor has been localized, surgeons can plan the interventional procedure in 3D by selecting the target and entry point. In this phase, the clinician can analyze the best approach to reach the tumor. Once the planning is done, clinicians can use the MAXIO®'s robotic targeting system to support them to reach the tumor safely and as planned, and then proceed to deliver the thermal or other energy beams to blast the tumor. Finally, the visualization tools help clinicians to verify and extend the procedure if needed. The robotic platform has been tested using abdominal phantoms [129]. Initial experiences with the system reported that it improves the accuracy of needle placement, reduce number of needle passes, and significantly reduce the total radiation dose to the patients [130].

3.5.2. Cardiac Surgery

Robots have been also applied to support the intravascular procedures. In this sense, Hansen Medical (Mountain View, CA, USA) developed the Sensei® robotic catheter, which is a master-slave system that allows surgeon to control remotely a fluoroscopically guided catheter. This system prevents the exposure to radiation by the cardiologist. Sensei® received the FDA clearance in 2007. This robotic system has a workstation with an intuitive interface that translates the surgeon's hands movements to a robotically steered guided catheter using advanced robotic technology (Artisan® Control Catheter). The combination of outer and inner guide motion allows the catheter to easily acquire any curved shape. The workstation provides the fluoroscopic view of the catheter as well as the 3D model of it. Sensei® is compatible with multiple imaging systems including fluoroscopy as well as 3D mapping systems. This system also provides force feedback thanks to a force sensor at the tip of the catheter that registers the information regarding the contact between the catheter and the tissue [131]. These features allow surgeons to navigate flexible catheters with greater stability and control during complex cardiac arrhythmia procedures. This system has been used extensively for catheter ablation of atrial fibrillation [132,133]. Studies reported that the use of this system reduces fluoroscopy times in catheter ablation of atrial fibrillation, resulting in reduced X-ray exposure for patients and other surgical staff in the OR [133,134].

Another feasible option for remote catheter navigation and ablation is the use of remote magnetic navigation technology. This technology is used by the Niobe® Navigation System (Stereotaxis, St. Louis, MO, USA), which was designed for cardiac interventions. This system consists of two permanent magnets positioned at either side of the fluoroscopy table creating a spherical uniform magnetic field, which can apply a low-intensity magnetic field to the patient. The system uses a special catheter containing small magnetic implants, which are aligned with regard to the magnetic field applied. The workstation of this robotic platform is able to integrate real-time imaging data to produce 3D magnetic vectors. This allows the cardiologist to guide the tip of the catheter through the major vessels and heart of the patient by changing the orientation of the magnetic field. The Niobe® system has been proven safe and effective in the treatment of different types of supraventricular and ventricular arrhythmias [135-137].

3.5.3. MRI-Compatible Robots

In 2008 Hashizume et al. [138] presented a MR image-guided surgical robotic system for MIS. The system consists of MR image guidance, an MRI-compatible operating table, an MRI-compatible master-slave surgical manipulator, and an open-bone MRI scanner (Figure 7). The master-slave robotic system is made of MRI-compatible material, and enables each manipulator to be attached to any position on the guide rail of the operating table. The manipulator system has four arms: one holds the endoscope while the other three arms hold the robotic forceps or other surgical instruments such as ablation needle, grasper, scissors or needle holder. All of them are MRI-compatible. The surgeon controls remotely the slave manipulators by means of a console, which also provides the image-guidance system and the endoscopic view. The image-guidance system allows surgeon to make a preoperative plan using the 3D anatomical images and see in real time the navigation images during the intervention in order to reach easily the target.

They performed in vivo experiments with MR image-guided laparoscopic radiofrequency ablation for liver tumors on three pigs, using mimic tumors made of agarose gel and with a diameter of approximately 2cm. In order to plan the puncture path, the surgeon segmented the target and defined the entry point on the abdominal wall using the MRI data on the preoperative planning system. Then, during the intervention the tumor was punctured using the MR image-guided surgical robotic system. The surgeon succeeded in puncturing safely all liver targets on each subject while maintaining the operative field with the robotic forceps [138].

Figure 7. MRI-guided surgical robotic system. The photograph shows an open-bone MR scanner in the top left, the MRI-compatible operating table with the compact MRI-compatible surgical manipulator (slave) in the upper right, and the surgical console with the manipulator (master) at the bottom (Courtesy of Prof. M. Hashizume, Department of Advanced Medical Initiatives, Kyushu University, Fukuoka, Japan).

Another MRI-compatible system for MIS is the MrBot® (Johns Hopkins Bayview Medical Center, Baltimore, USA). This is a fully-actuated robot for image-guided access of the prostate gland. The robot was customized for transperineal needle insertion and designed to be MRI-compatible. To achieve it the robot was made of nonmagnetic and dielectric materials such as plastics, ceramics, and rubbers and it is electricity free. The robot implements a pneumatic actuator to avoid electricity use. The robotic system consists of a controller unit located outside the imager's room, which has all the electric components, and the robot. The robot's end-effector has six DOF to be placed and oriented. This end-effector has an additional DOF to set the depth of needle insertion and three DOFs to manipulate a titanium needle. This robotic system has been designed to accommodate various needle drivers for different percutaneous interventions such as biopsy, thermal ablations, or brachytherapy. However, to date only the needle driver for the transperineal seed brachytherapy has been implemented. The tip of the robot has a MRI-visible set of markers to

register the position of the robot. Planning software is used for organ segmentation and defining the needle path. Dose constraints and organ contours are used by the planning software to determine the optimal location for the seeds. Needle penetration and source delivery are automated and controlled remotely by the surgeon [139]. This system was experimentally tested in 4 male dogs for prostate brachytherapy [140]. Results showed a mean placement error of the seeds of 3.32 ± 2.77 mm.

CONCLUSION

The introduction of computer-assisted surgery, including image-guided surgery and robot-assisted surgery, to support surgical interventions has provided surgeons with new assistance tools to address some limitations of MIS as well as improve the clinical outcomes. In general terms, the magnified operative field and the increased surgical dexterity result in a low conversion rate and reduced tissue trauma. With improved computer and imaging technologies, navigation systems are quickly becoming an integral part in the surgical routine in hospitals. These systems improve the surgeon perception of the patient anatomy and provide tools to analyze in advance the most suited approach to carry out a surgical intervention. In this sense, AR offers a suitable way to enhance the common view of the surgical field with useful information as preoperative images and virtual models. Although this technology is well established for rigid anatomy, further work has to be done for a full integration with deformable anatomical models. Continuous technological advances in robotic-assisted surgery have led to potential improvements in the development of MIS procedures such as 3D vision, increased precision and dexterity, and ergonomic conditions for the surgeon. Besides, novel robotic prototypes are being developed for recent MIS approaches such as LESS and NOTES. New dexterous and micro-robotic systems are able to enter the body via a LESS or NOTES approach, providing assistance during the surgical intervention. However, there is currently no ideal platform for these surgeries. Each kind of procedure may require a customized solution to provide a feasible surgical robotic system.

Chapter 47

MODIFIED METHODS OF SETTING UP THE SPINAL NAVIGATION SYSTEM

Sang Hoon Jang* and Ho-Yeon Lee

Department of Neurosurgery, Gang-buk Wooridul Spine Hospital,
Seoul, Korea

ABSTRACT

There are many reports about accuracy and efficacy of the spinal navigation system but most of their topics are limited to spinal instrumentation. For minimally invasive surgery, important things are how to set up navigation system fast and efficiently without interference of surgical flow, and how to use the navigation system within a small working field. Our team has already introduced a skin fixed dynamic reference frame (DRF) into mini open transforaminal lumbar interbody fusion (TLIF) and recently examined the accuracy of skin-fixed DRF in the anterior cervical foraminotomy. Both methods require only few minutes to set up and do not prohibit the natural movement of the surgeon during the operation. We want to share detailed methods about setting up the navigation system and the knowhow of using navigation systems, especially in minimally invasive spinal surgeries.

Keywords: spinal navigation system, skin fixed dynamic reference frame

1. INTRODUCTION

Recently a number of different manufacturers offer spinal navigation systems, which utilize preoperative CT scans to intraoperative 3D images, which are widely used in spinal surgeries [1-5]. Although there are some differences in hardware and software functions, these systems basically enable surgical instruments to be shown in reference to the displayed imaging anatomy in real time. Therefore, a more precise and delicate operation, after minimal exposure of the spinal structures could even be possible in deformed or severely degenerated

* Corresponding Author's Email: iamleesol@gmail.com.

spines [6]. There is a steep learning curve in using the navigation system, which is difficult and requires a significant amount of time, especially in the case of early experience of image guided surgery, even in a simple procedure [3-5]. Among every step of introducing the navigation system, the most important thing is the registration process for matching the image anatomy to the surgical anatomy. Setting reliable reference frames have an important role in reducing registration inaccuracy. Usually, setting up the navigation system is done with the fixed reference frame (FRF), which is attached to a head rest or operation table. But in this circumstance, the positioning change of the patient, on the operation table, can cause significant errors in the navigation system.

A dynamic reference frame (DRF) is firmly attached to the patient's body, which helps to overcome these weak-points. Bone fixed DRF usually requires another separate skin incision, or a longer incision, and occasionally interferes surgeon's movement. Skin fixed DRF can be a solution to these problems, and are designed as a fast and efficient method for minimal invasive surgery without interference of surgical flow and within a small working field.

2. MATERIALS AND METHODS

2.1. Indication

- Minimal invasive anterior foraminotomy in cervical spine
- Multilevel oblique corpectomy of cervical spine in case of ossified posterior longitudinal ligament (OPLL) or cervical spondylotic myelopathy (CSM)
- Minimal invasive posterior cervical foraminotomy
- Posterior cervical instrumentation
- Thoracic posterior decompression surgery using a tubular retractor
- Pedicle screw insertion in thoracic spine
- Paraspinal decompression for extraforaminal lumbar disc herniation,
- Mini open transforaminal lumbar interbody fusion (TLIF).

2.2. Instrumentations

- Cone beam CT(O arm® Medtronic Sofamor Danek, Memphis, TN) (Figure 1)
- Navigation system (Stealthstation® Medtronic Sofamor Danek, Memphis, TN) (Figure 2).
- Incised surgical film (OPSITE® Smith & Nephew, Hull, UK) (Figure 3).
- Dynamic reference frame (DRF) (Figure 4)

2.3. Procedures

Anesthesia

General anesthesia with single lumen endotracheal tube

If a monitoring system for motor and somatosensory evoked potentials is required, set up prior to positional change

Figure 1. Cone beam CT(O arm® Medtronic Sofamor Danek, Memphis, TN)

Figure 2. Navigation system (Stealthstation® Medtronic Sofamor Danek, Memphis, TN).

Figure 3. Incised surgical film (OPSITE® Smith & Nephew, Hull, UK)

Figure 4. Dynamic reference frame (Stealthstation® Medtronic Sofamor Danek, Memphis, TN)

Figure 6. Exposed forehead is covered by transparent surgical film.

Figure 7. Mount the DRF cutaneously, overlying the draped forehead and fix it firmly with incised surgical film.

Thoracic spine

Prone position

While draping the patient, expose the skin surface widely to the lumbar spine and cover with transparent surgical film (OPSITE® Smith & Nephew, Hull, UK). Mount DRF on the skin surface, 5-6 levels below the surgical point, and fix firmly with incised surgical film (OPSITE® Smith & Nephew, Hull, UK)

Lumbar spine

Prone position

While draping the patient, expose the skin surface widely to the sacral hiatus area. Cover with transparent surgical film (OPSITE® Smith & Nephew, Hull, UK). Mount dynamic reference frame on the skin surface of sacral hiatus, and fix firmly with transparent surgical tape (OPSITE® Smith & Nephew, Hull, UK) (Figures 8-10).

Figure 8. During the draping, expose skin surface widely to the sacral hiatus area.

Figure 9. Exposed sacral region is covered by transparent surgical film.

Figure 10. Mount the DRF cutaneously overlying the draped sacral hiatus area and fix it firmly with incised surgical film.

2.4. Outcomes

From June 2009 to Dec. 2009, 20 patients underwent mini-open TLIF with skin fixed DRF [7]. Mean age was 55.9 years (range: 34–74 years) and mean BMI was 24.4 (range: 19.9–28.6).

Five patients were diagnosed with spondylolytic spondylolisthesis, and the remaining fifteen patients were diagnosed with degenerative spondylolisthesis. Nineteen patients underwent single level surgery and 1 patient underwent two level surgery. A total of 82 screws were inserted under navigation guidance with skin fixed DRF. The mean time duration to set up the navigation system with skin fixed DRF was 8.5 ± 6.5 min (range: 10–30 min). The second O-arm scan, after pedicle screw insertion, revealed eight pedicle breaches (4 grade I, 2 grade II, and 2 grade III) [8]. Among them, the two grade III screws were reinserted and confirmed to be in the proper position with a third O-arm scan. Despite the eight pedicle perforations, there were no major complications such as nerve injury, unintended durotomy, or malposition of the final construct.

Cervical Spine

From September 2012 to May 2013, 31 patients underwent minimally invasive anterior cervical surgery. A single level surgery was done in 10 patients; two level surgeries in 11; and three level surgeries in 10. The mean time duration to set up navigation system with skin fixed DRF was 4.8 ± 3.5 min. (range: 8–20 min). 48 Caspar pins were inserted into each cervical vertebra. The validity of the navigation was then assessed by comparing the differences between the actual positions of the inserted Caspar pin, based on the second O-arm scan and the recorded images of the navigation probe. The mean horizontal error was 0.49 ± 0.71 mm. The mean vertical error was 0.88 ± 0.93 mm. And the mean angular deviation in the sagittal plane was $0.59 \pm 0.55^\circ$. ICC value was 0.74 for intra-observer reliability. And there were no major complications or revision surgeries due to the navigational error. But unintended durotomy developed in 3 cases without any neural injury; all of them had severe space-occupying calcified OPLL, however, in all cases, in-situ dura repair was done with artificial dura.

CONCLUSION

With development of the navigation system, the spine surgeon can perform complex and minimal invasive surgery successfully without radiation hazard, but many surgeons are still do not favor the navigation system and don't trust it, due to the complex methods for registration and the set up process, learning curve, and the interruption of work flow. This modified method will be one part of the solution to overcome these kinds of problems.

Lisboa, Portugal

ABSTRACT

Robotic surgeries are performed by classical techniques, purely mechanical and their success essentially depends on the surgeon's experience. However, surgeons are increasingly receptive to new technologies and search new tools that help them improve their performance. Increasing advances in robotics have allowed the emergence of new systems dedicated to surgery, which began to be a valid option in surgical aid. The computer-assisted surgery (CAS) and particularly the robot-assisted surgery, improves accuracy and precision of procedures, allowing more reliable and reproducible outcomes, minimizing the invasiveness of surgical procedures and improving patient outcomes by reducing complications and improving patient safety compared with conventional techniques. The increasing evolution of surgical robotic systems has also been accompanied for significant evolution in surgical navigation systems.

Actual systems, commonly used in the operating room, employ markers placed on the human for tracking bones or other body parts. Ultrasound images are on the rise, and under strong development for use in surgeries, allowing low-cost and non-invasive real-time navigation systems.

These navigation systems will be used in the near future in CAS and robotic surgery. The chapter will review the current approaches in robotic surgery, where ultrasound based navigation is used, with a special care on orthopedics.

Keywords: ultrasound imaging, robotics, surgical robotics

1. INTRODUCTION

Increasing advances in robotics have allowed the emergence of new systems dedicated to surgery, which began to be a valid option in surgical aid. The computer-assisted surgery (CAS) [1] and particularly the robot-assisted surgery [2, 3] improves accuracy and precision of procedures, besides producing more reliable and reproducible outcomes, minimizing the invasiveness of surgical procedures improving patient outcomes by reducing complications and improving patient safety compared with conventional orthopedic techniques.

The use of robots to automate medical tasks increases its reliability, accuracy and is an excellent contribution to Minimal Invasive Surgery (MIS). MIS is becoming more and more common nowadays in hospitals. These procedures through tiny incisions are performed instead of one large opening. Because the incisions are small, patients tend to have quicker recovery times and less discomfort than with conventional surgery. Last thirty years have been marked by the development of robotic systems for MIS. In 1985 a robot, The PUMA 560 [4] was used to place a needle for a brain biopsy using CT guidance. Three years later the same machine was used to perform a transurethral resection. In 1987 robotics was used in the first Laparoscopy surgery, a cholecystectomy. In 1988, PROBOT, [5] developed at Imperial College London, was used to perform prostatic surgery.

More recently appeared the following surgical systems: ZEUS, DaVinci and DLR MIRO. The ZEUS robotic surgical system, initially developed in 1995 for endoscopic microsurgery (including general surgery, thoracic surgery, gynaecology, urology), was the robotic system used in the first transatlantic surgical intervention performed on a human, in 2001 between New York and Strasbourg, France, at 15000 km of distance [6]. The DaVinci Surgical System enables surgeons to operate through a few tiny incisions with dramatically enhanced vision, precision and control. State-of-the-art DaVinci Surgery helps surgeons to minimize the pain and risk associated with traditional surgery, while increasing the chances for a fast recovery and excellent clinical outcomes. DLR MIRO [7–9] is a compact, slim and LightWeight Robot (LWR) robotic system versatile for various existing and future medical robotic procedures. It can be used in orthopedics for setting holes for bone screws, robot-assisted endoscope guidance and on to the multi-robot concept for (endoscopic) minimal invasive surgery.

2. ORTHOPEDIC ROBOTIC SURGERY

In orthopedics several solutions have emerged, such as ROBODOC® [10], for the planning and performance of total hip and knee replacement, CASPAR® [9], developed for the same purpose of ROBODOC®, Acrobot Sculptor [11, 12], used in knee surgery, or the RIO robotic arm (MAKOplasty) [13], the latest developed system for orthopedics. The Robodoc® surgical system consisted of the Orthodoc® [14], pre-surgical planner and the Robodoc® as the surgical tool. The Robodoc system comprises a five-axis Sankyo-Seiki industrial robot with a six degree-of-freedom force-sensor. The Orthodoc® describes the three-dimensional geometry of the femur from CT data and the geometry of the implant. The MAKO system consists of the well known general purpose WAM - Whole Arm Manipulator from Barrett Technology [15], for bone deburring and an optical navigation system consisting of stereo infrared cameras, and marker arrays attached to the tibia and femur. On the other

hand, the Acrobot system uses their special purpose robot manipulator, while the tibia and femur are immobilized with bone clamps which are fixed through small skin incisions.

These first systems evolved with the massive usage of the computer in the operating room, as presented in the following section.

3. COMPUTER AIDED ORTHOPEDIC SURGERY

The increasing evolution of surgical robotic systems has also been accompanied by significant evolution in the surgical navigation systems [16]. Of the several systems that have appeared in the market are highlighted the OrthoPilot [17], (<http://www.orthopilot.com>) and the BrainLAB systems [18], (<https://www.brainlab.com>). Both systems employ markers placed on the femur for tracking the bone movements [19].

The incisions performed to place these markers can leave serious injury to the patient and there are many cases of complaints of pain at the implant site after Surgery. Studies on the patients reported persistent severe pain at the site of pin implantation, after surgery, caused by the injuries to the nerves, caused by fiducial markers [20].

Surgical navigation systems allow the surgeon to perform surgical actions in real time using information conveyed through a virtual world, which consist of computer-generated models of surgical instruments and the virtual representations of the anatomy being operated. Virtual representations can be generated from data obtained through Computer Tomography scans, ultrasound images, amongst others. Image-guided surgical navigation is on the rise in many different areas of medicine, with strong growth in orthopedic surgery.

The use of visual information obtained from medical images is widely used in Computer Aided Orthopedic Surgery (CAOS) (www.caos-international.org). CAOS systems are increasingly available, with several commercial and research systems now well established. These systems assist surgeons in preoperative planning and simulation, from the obtained bone model, and in intra-operative navigation, using tracking systems with fiducial markers attached to the patient bone, and in the robotic execution of the surgical procedure. From the fiducial markers the position and orientation of the bone in the intra-operative scenario relative to the robot frame is obtained in the state-of-the-art systems, e.g., the Brain Lab System or Orthopilot.

Much research has been developed in order to find new solutions and explore alternatives to avoid the fiducial markers in surgical navigation, [21, 22]. The use of Ultrasound (US) images has gained high relevance in Image-guided surgeries, [23, 24], since it is a non-invasive modality and provides real-time images, which are used to plan a surgical procedure and guide surgical instruments during surgery. The ultrasound based 3D bone surfaces are located by placing markers in the US probe to track them and generating a 3D bone surface that can be registered with a model preconceived through a 3D image modality, as Computed Tomography (CT) or Magnetic Resonance Imaging (MRI).

4. TOWARDS ULTRASOUND IMAGING IN ORTHOPEDIC SURGERY

Recently, much scientific research work has been developed, with the purpose of eliminating fiducial markers in orthopedic surgery [25, 26], and the main guidelines of research focuses on the use of intra-operative Ultrasound (US) images and pre-operative computed tomography (CT) to provide real time surgical guidance. In [27], it is presented a semi-automatic bone detection approach for US via registration with CT datasets pre-operatively acquired. The CT data is used to create a patient-specific bone model, and rigid transformation from US to CT is estimated by the Iterative Closest Point (ICP) algorithm, from a initializing of three points in the datasets. The three correspondence points, define the principal axis and orientation of the bone in both modalities. In [28] is proposes a point-based registration algorithm based on unscented Kalman filter (UKF) to estimate the rigid transformation parameters between the bone surfaces obtained from US and CT data, less sensitive to outliers compared with ICP.

Both methods are based on features of the datasets (feature-based), but there are also methods that use the image intensity information (intensity-based) directly in order to avoid extraction of bone surfaces. In [29] was used the normalized cross-correlation as a similarity metric for registering CT and US images. Prior to registration, both datasets were converted to bone probability images using gradient, bone intensity and US shadowing artifact information. More recently, in [30] it is proposed a rigid registration method where the translation parameters are estimated from the projections of local phase volumes in frequency domain. Bone surfaces were automatically extracted directly from 3D US and CT volumes based on 3D local image features calculated using 3D Log-Gabor filter.

After its incipient first experiments, guiding a robot using ultrasound images, i.e., ultrasound based visual servoing, has recently gained new interest due to the establishment of visual servoing.

Initial works consisted in the use of robot arms that manipulated an ultrasound probe for medical diagnoses [31, 32]. The use of ultrasound also found its way into orthopedics as a non-invasive radiation-free navigation system for surgeon operated, interventions [33]. This is particularly valuable when the bones to be operated are so small, that it is not possible to attach heavy tracking targets onto them. For interventions cooperated by robot arms, effective applications using ultrasound guidance are not yet available, but an intense race involving research centers and industry is currently taking place.

Guiding a robot in positioning tasks through visual information using uncalibrated visual servoing systems is a very active research topic due to the complexity of real applications and workspace scenarios such as an operating room. The operating room can unpredictably change during a surgery, causing calibration errors. In [34], uncalibrated visual servoing was proposed, where the inverse system Jacobean was estimated on-line, thus immune to camera miss-calibration. It presents a very promising solution for the operating room, where it is also desired to minimize calibration time. Furthermore, this approach will give added robustness to a medical setting where the environment is calibrated, but redundancy is necessary for safety reasons. This work has been further extended to a more general case in [35], where the uncalibrated model can evolve during the tasks to be performed. In [36], tools for ultrasound based 3D Bone model reconstruction; registration and visualization are presented, which are currently being developed by the research team, in order to introduce ultrasound feedback in

the visual control loop. In [37], was proposed an approach to obtain the position and orientation of a bone based in its 3D model obtained from Computed Tomography images (in the preoperative scenario) and the registration of ultrasound images to it (in the intraoperative scenario). More recently, in [38], was proposed a vision system for robotic ultrasound guided orthopedic surgery. This system, during surgery, acquires a 3D US bone surface from a sequence of US images. Later, that bone surface will then be registered to the pre-operative 3D bone model, for a precise knowledge of the bone position and orientation. The system then allows bone tracking during surgeries based on ultrasound images of bones, without the use of fiducial markers, diminishing invasiveness, is briefly presented in the next section.

5. ULTRASOUND BASED NAVIGATION FOR ORTHOPEDIC SURGERY

For navigation, the system presented in [38], during surgery, acquires a 3D US bone surface from a sequence of US images. This bone surface will then be registered to the pre-operative bone model, for a precise knowledge of the bone position and orientation. This registration is performed in two steps. Firstly a global registration is performed, before the surgical procedure, to exactly register the bone. The second step is to locally register the bone, which is faster and more suitable for tracking the bone movements. To update the bone's drilling position and orientation, the robot manipulator uses the measured bone movement. Figure 1 shows an overview of the HipRob navigation system [38].

Figure 1. Overview of the hardware setup and frames transformations of HipRob navigation system [38].

The avoidance of fiducial markers implies that the US probe is referenced to the optical measurement system (NDI - Polaris) (<http://www.ndigital.com/medical/products/polaris-family>). Placing on marker in the US probe makes the referencing. From this moment, also the images and features are referenced to the tracker. The pose of the robot end-effector also has to be referenced by the Navigation system to inform the robot controller of its location. The ideal drilling point is obtained pre-operatively in the CT reference frame. Inside the operating room, an initial calibration (${}^{CT}T_{NDI}$) between the tracker and CT is needed to localize the femur. After calibration, the main goal consists in to determine at each instant, the drilling point in the robot reference frame (${}^{ROB}P_{drill}$) and track the bone movements with the robot.

CONCLUSION

The present chapter presented the most important steps that surgical robotics are performing towards a common use in the operating room. The control of robots is evolving at an enormous pace and is strongly pushed by the recent advances in medical imaging. Ultrasound imaging plays a decisive role in robotic surgery because it is noninvasive and widely used by medical doctors. The main drawback is the precision of the measurements taken from US images. It was shown that this error is less than 2 [mm] nowadays, which allows its use in the operating room during surgeries. These types of systems are still slow, and cannot be operated in real-time, although they can give a measure to correct the robot trajectory. Future developments in this field will surely take care of diminishing the computational time, and also the precision of the system.

The HipRob navigation system was applied with real results in a femur phantom developed by the authors, assuring a precise calibration scheme, below 2 [mm] error, [35] which allows the ultrasound system to track the femur movements.

Chapter 49

DEVELOPMENT OF SCRUB NURSE ROBOT (SNR) SYSTEMS FOR LAPAROSCOPIC SURGERY

Kitaro Yoshimitsu*

Institute of Advanced Biomedical Engineering and Science (TWIns),
Faculty of Advanced Techno-Surgery (FATS), Tokyo Women's Medical University,
Tokyo, Japan

ABSTRACT

There is currently a chronic shortage of scrub nurses to exchange surgical instruments with operating surgeons. Smooth instrument exchange maintains a surgeon's operating rhythm and can be limited by the availability of skilled scrub nurses. To compensate for this shortage, we propose a scrub nurse robot (SNR), which will achieve an efficacy at the level of a skilled human scrub nurse during laparoscopic surgery. In this paper, we developed a new SNR with a novel function: automatic insertion of a surgical instrument to achieve a smooth instrument exchange with the expectation that the higher functional ability would increase surgical operation efficacy. First, we developed the first version of the SNR, which was composed of two separate robots called R-1 and R-2. The R-1 was designed to have two arms to handle an electric knife and a blood aspirator, which are the instruments that are most frequently used during laparoscopic surgery. The R-2 has a horizontal arm and two hands. The R-2 also has a tool changer that stores other instruments. After the basic validation study of the first SNR, the second version of the SNR was developed and achieved smooth and wide movement of its arms, each with four degrees of freedom (DOF). The second SNR is able to speak several sentences and recognize some words, as well as the names of surgical instruments, and is also capable of recognizing a surgeon's intraoperative actions by a real-time visual recognition system (RTVRS). The RTVRS is basically composed of both a commercially available three-dimensional (3D) position-tracking system and the algorithm that we developed to recognize the surgeon's actions during the exchange of instruments from the aforementioned positional data. Considering the results from the validation study of the second SNR, the third version of the SNR, which is able to insert the tip of the instrument into a small-caliber trocar cannula penetrating a patient's abdominal wall, was developed.

* Corresponding Author's Email: yoshimitsu.kitaro@twmu.ac.jp.

This function is called the automatic instrument inserting function (AIIF). The AIIF's algorithm, which is called kinematic-based feedback control, enables the arm instead of a surgeon to insert the instrument into the cannula. We validated that it was quicker to use the third SNR to help the surgeon's stand-ins to exchange instruments in a laboratory using the second SNR compared to human scrub nurses in real surgical operations. We defined the time spent exchanging surgical instruments as the *targeting time*. The results of the evaluation showed that it was possible to exchange instruments 1.69 s faster than in a clinical operating room between a human scrub nurse and a surgeon and 2.8 s faster than using the second SNR.

Keywords: laparoscopic surgery, robotic scrub nurse, automatic instrument inserting function

1. INTRODUCTION

Large hospitals continue to face a chronic shortage of nurses. The shortage is especially dire for scrub nurses who assist surgeons by exchanging surgical instruments [1, 2]. A scrub nurse is required to hand a surgical instrument to an operating surgeon as soon as it is requested. It may cause a distraction during the overall procedure if the scrub nurse spends too much time looking for the instrument. This lag may place an unnecessary burden on the surgeon, possibly reducing the quality and efficacy of the operation. To avoid such delays, the scrub nurse needs to be fully attentive to the activity in the operative field and also accurately anticipate what instrument a surgeon might need in the next procedure. For this to be possible, the scrub nurse needs to know the surgical procedure and the surgeon and also must be highly disciplined. An ideal scrub nurse is defined as someone who is able to meet the aforementioned requirements; as such, ideal scrub nurses are scarce. To compensate for the severe shortage of scrub nurses, a scrub nurse robot (SNR) system has been proposed. The goal of this research project was to develop an SNR capable of acting like the aforementioned skilled scrub nurse. The SNR was designed to adapt to surgeons with various levels of skill and different personalities. Three versions of SNR systems have already developed for endoscopic and laparoscopic surgery. The target for this SNR system is laparoscopic surgery because it is not too complicated for the SNR to follow, and surgeons performing endoscopic and laparoscopic surgery do not use as many types of surgical instruments as in conventional surgery in which the abdominal or thoracic wall is cut open widely [3].

Robotic scrub nurses to pass surgical instruments have been extensively proposed and investigated. The Penelope Surgical Instrument Server (SIS) is a robotic scrub nurse that has been used in clinical cases [4]. It can hand surgical instruments to surgeons per voice commands. This robot seems to be designed for so-called minor surgeries. Takashima et al. [5] have developed an interface between their own developed robotic scrub nurse and a surgeon, although the system has not yet been used in actual clinical cases. However, the SNR system that is proposed herein is intended to be used during major surgery such as abdominal, thoracic, and cardiac surgery. Moreover, the goals of the SNR are for it to be able to accurately anticipate which instrument the surgeon will request for the next step of surgery and to hand this to the surgeon in a timely fashion.

2. METHODS

2.1. First Version Of SNR

Figure 1 shows the first version of the SNR: R-1 and R-2 [6, 7].

The specifications of the R-1 (Figure 1a) were determined from analysis of the intraoperative motions of a surgeon and a scrub nurse in laparoscopic surgery [2]. In the preliminary investigation of a laparoscopic cholecystectomy, an electric knife and a blood aspirator were used very frequently (for approximately 40–50% of the duration of the laparoscopic procedure). The analysis of the intraoperative motion data indicated the necessity for the robot, which handles only an electric knife and a blood aspirator, and it was decided to divide the required tasks into two robots. The R-2 (Figure 1b) was designed to handle other instruments. The total number of instruments was, at the most, 15 in a routine laparoscopic cholecystectomy. Further details about the R-1 and R-2 are described in the next chapter.

Figure 1. The first version of the SNR: R-1 and R-2.

The R-1 has a linear actuator inside its main body to lift the arm up and down to the height position of the surgeon's hand. A rotary actuator is located on this linear actuator to move the shoulders. In the wrist section, in order to realize a smooth transfer of instruments, a rotary actuator is fitted for each wrist. In the fingers, pneumatic robotic hand actuators are used to tightly grasp instruments. The R-1 has six degrees of freedom (DOF). Motor drivers and power supplies that control the actuators are located in the head section.

Figure 1b shows the R-2. The R-2 has a tool changer component and an arm component side by side. The tool changer holds a laparoscope, forceps, and the other instruments, and the

arm component hands over and receives the instruments with its two hands. The tool changer has a pneumatic latch rotor actuator to transfer the instruments to the hand. The arm turns 180 degrees to pass them to the surgeon after retrieving the instrument from the tool changer. The fingers of the R-2 are moved by the same air-powered mechanism as that of the R-1 to tightly grasp instruments. The tool changer and arm components both have linear actuators for height adjustment according to the hand position of the surgeon. The R-2 has nine DOF.

Figure 2. The second version of the SNR: ASULA.

2.2. Second Version of SNR

Considering the results from the validation study, a second version of the SNR—termed the advanced surgical unit in laparoscopic area (ASULA)—was developed. Figure 2 shows the ASULA. The biggest change from the first version of the SNR was that the separate robots were combined into one ASULA because the first SNR was too large for ordinary operating rooms. Therefore, the working space for an SNR in an operating room is expected to be decreased, and the dangers of interference with other surgical systems and instruments could be reduced. In order to abandon the R-2's main component of the tool changer—a surgical tray, which generally holds sterilized surgical instruments—was located at the side of the ASULA. The number of DOF in the arm sections was increased to four. While the arms were now freer, use of the rotary and linear actuators was maintained. Therefore, in the second version of the SNR, a reduction by five DOF from the first version of the SNR was incorporated to offer a total of 10 DOFs. This means that even if by any chance a malfunction should occur in the SNR, safety would be improved because of the expected greater simplicity of the control program. As for the user interface, in addition to foot switches that

were already installed in the first version of the SNR, a speech recognition system (Voice Key ver. 1.4) was employed to improve human adaptation.

2.3. Real-Time Visual Recognition System for Second Version of SNR

We intended to develop an SNR that was capable of providing the correct instrument without any verbal requests from the surgeon and without any delay. For this to be possible, the SNR needed a real-time visual recognition system (RTVRS) to detect the characteristics of surgeons' motions when exchanging instruments, especially to detect the moment when they draw out an instrument after use.

First, we defined and divided the intraoperative actions of a surgeon into two groups: *working* and *exchanging* actions. The *working* action means that a surgeon is doing some kind of surgical procedure with a surgical instrument, and the *exchanging* action means that he or she is replacing the surgical instrument after use with the instrument that is needed next. During this exchanging action, a scrub nurse must help the surgeon in an accurate and timely manner. The exchanging action was, for the purpose of convenience, further subdivided into five key actions: (1) pulling an instrument after use through a trocar cannula; (2) returning the instrument; (3) waiting for an instrument that the surgeon has requested; (4) receiving it; and (5) inserting it into the trocar cannula.

An algorithm capable of detecting and distinguishing the surgeon's motions observed during the action of exchanging instruments was developed [8, 9]. Reflective markers were attached to the surgeon's wrist, elbow, shoulder, and chest. These markers were captured by two digital video cameras set up in the operating room. We verified whether the algorithm was capable of detecting and distinguishing the six motions observed during the aforementioned five actions. As a result, the algorithm correctly captured each motion in real surgical operations [8, 9]. The entire procedural model of an endoscopic and laparoscopic surgery was constructed for the actions of a surgeon, a scrub nurse, and the possible statuses of a patient [2, 8, 9, 10] using the extended timed-automata formalism of UPPAAL [11, 12]. This surgical model installed into the SNR can enable the SNR to know which procedure is occurring to confirm which action a surgeon is now conducting and possibly to recognize what type of surgery is happening. The aforementioned surgeon's actions can be constructed by extended timed-automata modeling, as shown in Figure 3.

The composition of the first version of the RTVRS for the SNR was aimed at detecting surgeons' motions during the exchange of instruments, although the goal for the RTVRS for the SNR is to establish a visual system that enables the SNR to recognize surgical personnel actions and surgical instruments' positions in real time. First, in order to obtain real-time positional data of a surgeon's body parts, a commercially available real-time three-dimensional (3D) position-tracking system was utilized. This consists of high-speed digital video cameras with a sampling rate of 60 frames/s and QuickMag IV, which is capable of automatically tracking colored markers and outputting their 3D coordinates. More than two digital video cameras must be used in order to provide 3D positional data. Second, we modified the aforementioned algorithm for offline analysis of a surgeon's motions in order for the SNR to recognize the surgeon's actions in real time from the 3D positional data output by the QuickMag IV. One of the main modifications was that the modified algorithm detected only two out of the six actions shown in Figure 3: extracting and inserting [13].

Figure 3. The aforementioned surgeon's actions during laparoscopic surgical procedure.

2.4. Third Version Of SNR

Precise analysis during endoscopic and laparoscopic surgery provided us with various types of intraoperative information and findings. For example, the exchange of surgical instruments is repeated 60 to 150 times in a single laparoscopic cholecystectomy, and each action of exchanging surgical instruments takes quite a long time—on average, 4–5 s. As mentioned in the previous section, we further investigated the surgeon's actions of exchanging instruments by dividing these into five subactions, such as extracting an instrument, returning it, waiting for the next instrument, getting it from a scrub nurse, and inserting it through a trocar cannula into the operative field. We found that an older, more highly skilled surgeon spent more time inserting a surgical instrument into an inlet of a small-caliber trocar cannula than a younger novice surgeon did, although he finished the surgical operation much more quickly [7]. The action of inserting instruments into small-caliber trocar cannulas can be stressful for older surgeons because they must repeat this action many times. This action can also be unfavorable for young surgeons, although they are able to finish this action in shorter periods of time because they repeat this action many more times—sometimes amounting to 150 times in a single operation—than older, more highly skilled surgeons. Then, we came up with an idea for a new function of the SNR: an automatic instrument inserting function (AIIF). Namely, we considered that the SNR would be extremely helpful for all surgeons if the SNR instead of surgeons could insert surgical instruments into trocar cannulas. We also noticed another unfavorable action during endoscopic and laparoscopic surgery. The action of exchanging surgical instruments forces surgeons to shift their eyes from the endoscope monitor displaying the operative field. This action—called *eye-off* action—is distracting to surgeons because they like to keep their attention on the operative field. This aforementioned new feature of the SNR may eliminate

this unfavorable action because surgeons will not need to look at the inlet of the trocar cannula.

According to the concept of the new feature, we developed the third version of the SNR (Figure 4). The SNR is composed of three parts: an arm, a tool changer, and a body. The arm handles an instrument and guides the tip to the entry point of a cannula. The tool changer locates the upper part of the body with the tool stage. Each holder on the tool stage grasps a surgical instrument. The body contains a power supply, electric air valves, and motor drivers in a control box at the bottom of the body.

Figure 4. The third version of the SNR.

The entire arm can be detached at the shoulder by sliding respective counterparts in or out that are mutually complementary in shape. Two pneumatic actuators are used on the detachable section instead of an electric actuator in order to be sterilized. One of the actuators has two fingers and is used with a hand part to grasp an instrument with a 10-mm stroke. An infrared sensor is located on this actuator to detect objects between the fingers. The other pneumatic actuator is located at the wrist part. This actuator is used to retrieve an instrument from the tool changer. Electric drive actuators are used for the reaching mechanism, and a rotating mechanism is located at the shoulder. The shoulder rotation is correctly transmitted by using concavo-convex parts. The main shafts of the arm are made of carbon materials that are rigid and light. Every joint is made of an aluminum alloy with a black alumite treatment to prevent corrosion. Shafts in the joints are made of stainless steel with oil-less bearings. The tool changer has 10 tool holders that are positioned circularly, facing outward. This holder is designed to be detachable, similar to the arm. Each holder is composed of a pneumatic actuator and an infrared sensor to detect an instrument that is returned between the fingers. Stainless steel plates are affixed to the tip of the actuator to tightly hold an instrument. The tool stage on the tool changer is made of white MC nylon. Air pressure and electric supply for

the pneumatic actuators are supplied from the control box at the bottom. At the connecting part between the tool stage and the tool changer, we used air and electric connectors to transfer air pressure and electric signals. Thus, the tool stage can also be easily detached, much like the arm.

2.5. AIIF

The greatest characteristic of the third SNR is the AIIF of its arm. The arm inserts the tip of an instrument into the entrance of the trocar cannula instead of a surgeon. The AIIF has two purposes. One of these is reducing the waiting time; this forces a surgeon to wait for the next instrument until a scrub nurse hands it to him or her—1.71 s on average. The other purpose is decreasing the eye-off time, which takes 1.41 s on average when a surgeon inserts an instrument into the trocar cannula. Inserting an instrument with a length of approximately 400 mm into a 5-mm-diameter trocar cannula can be a difficult task, especially for older surgeons. If this annoying task were done automatically by the SNR, the operating procedure would be expected to become much smoother. To achieve this feature, a 3D coordinate measurement system named Micron Tracker 2 (Claron Technology Inc.) was used as the position feedback sensor. This system obtains the 3D coordinate and angle values of specific predefined markers. In this paper, we propose kinematic-based feedback control as a controlling algorithm for the AIIF. To achieve this idea, the original position of the SNR coordinate system was set as an absolute coordinate system; reference vectors were also created, as shown in Figure 5.

Figure 5. A controlling algorithm for the AIIF.

The AIIF was executed as follows:

- First, for the direct kinematic analysis, we described the 3D position of the tip of the instrument, as shown in Equation (1).

- Second, the 3D position of the tip of an instrument and the entrance of the trocar cannula were fed back by the Micron Tracker 2 and assigned to P_x , P_y , and P_z and P'_x , P'_y , and P'_z , respectively.
- Third, Equation (1) was solved for simultaneously. To solve the simultaneous equations, the value of θ_1 was fixed as 45 degrees.
- Finally, the values that should be controlled by each actuator were calculated via Equations (2)–(4) by using the solutions of Equation (1).

$$\begin{cases} (P_x, P'_x) = \mathbf{r}_0 - S_1(\mathbf{l}_0 + \mathbf{r}_2) + (S_1S_3 + S_2C_1C_3)\mathbf{l}_2 - S_1\mathbf{r}_3 + S_2C_1(\mathbf{r}_4 - \mathbf{l}_3) \\ (P_y, P'_y) = C_1(\mathbf{l}_0 + \mathbf{r}_2) + (-S_3C_1 + S_1S_2C_3)\mathbf{l}_2 + C_1\mathbf{r}_3 + S_1S_2(\mathbf{r}_4 - \mathbf{l}_3) \\ (P_z, P'_z) = -\mathbf{r}_1 - \mathbf{h} + C_2C_3\mathbf{l}_2 + C_2(\mathbf{r}_4 - \mathbf{l}_3) \end{cases} \quad (1)$$

$$\theta_1 = \theta_1^{SNRbody} - \theta_1^{SNRbody} \quad (2)$$

$$\theta_3 = \theta_3^{SNRbody} - \theta_3^{SNRbody} \quad (3)$$

$$\mathbf{h} = \mathbf{h}^{SNRbody} - \mathbf{h}^{SNRbody} \quad (4)$$

2.6. Evaluation of Third SNR Compared with Previous Version

In this section, we tested how fast the SNR inserts the tip of an instrument into the entrance of the trocar cannula. Four students were used as the surgeon's stand-ins in this experiment. They were all familiar with the role of a surgeon. We measured the time that was taken for the AIIF and defined this time as the *targeting time*. This targeting time starts from the moment when the tip of instrument is extracted from the entrance of the cannula. Measurement is finished at the moment when the tip of the next instrument is inserted into the cannula.

The SNR started moving from its waiting position. The signal from the infrared sensor was the trigger signal for starting the AIIF. After insertion, the surgeon's stand-ins could recognize the end of the targeting motion from a beeping sound from the computer. Then, they pushed the foot switch next to their feet. Finally, the SNR released the instrument and moved back to its original position, ready for the next motion.

The results are shown in Table I; Figure 6 shows the time taken for each segmented action. We segmented these actions based on the following definitions:

Returning: The moment from when the tip of the instrument is extracted to the moment when the surgeon releases the instrument.

Waiting: The moment from when the surgeon releases the instrument that he or she has finished using to the moment when the surgeon receives the instrument that he or she requested for the next operating procedure.

Targeting at the entrance of the cannula: The moment from when the surgeon receives the instrument that he or she will use in the next operating procedure to the moment when the surgeon inserts the tip of the instrument into the entrance of the cannula.

Mechanical movement: The moment from when the infrared sensor recognizes the extraction and the SNR starts moving to the moment when the SNR inserts the tip of the instrument into the entrance of the cannula.

Table 1. Time for targeting an instrument (in seconds)

Average	$\pm$ Standard deviation	Maximum	Minimum
Surgeon: real nurses ($N = 128$)	3.72 ± 2.19	17.70	1.77
Stand-ins: second SNR ($N = 27$)	4.80 ± 0.90	6.60	2.93
Stand-ins : third SNR ($N = 20$) (Kinematic-based feedback control)	2.03 ± 0.10	2.24	1.86

The targeting time in the case of the laboratory was considerably shorter and more stable than in the case when the second SNR was used, even compared to real operations. In particular, we determined that the third SNR finished its targeting motion 1.69 s faster than clinical cases under kinematic-based feedback control. We also observed that three-fourths of the stand-ins quickly adjusted to exchanging instruments with the SNR. Afterward, most of the time, they had already or concurrently grasped the handle of the instrument when the AIIF finished. Thus, all they had to do was quickly slide in the instrument as soon as the AIIF had finished. Therefore, if this arm is introduced in clinical operating rooms, we can expect that surgeons would concentrate more on the operating procedures because the SNR would enable them not to have to pay attention to confirming the position of the entrance of the trocar cannula as surgeons do currently.

Figure 6. The time taken for each segmented action.

CONCLUSION

To compensate for the severe and chronic shortage of scrub nurses, we have proposed an SNR system that is capable of functioning as a skilled human scrub nurse in endoscopic and laparoscopic surgery. We have proposed and developed three versions of this system. In this paper, we describe these three versions of the SNR and its features. The first SNR, which was composed of two separate robots called R-1 and R-2, was designed as a prototype. After the basic evaluation of the first SNR, we developed the second version of the SNR, which has a voice recognition system as a user interface and achieved smooth and wide movement of its arms, each with four DOF. The second SNR was able to speak several sentences and recognize some words, as well as the names of surgical instruments, and was also capable of recognizing a surgeon's intraoperative actions by its RTVRS. Concerning the results from the evaluation of the second SNR, we developed the third version of the SNR, which has an AIIF. This function (instead of a surgeon) correctly inserts the next instrument into the cannula. We constructed two types of algorithms for AIIF control and evaluated how well the third SNR worked in a laboratory compared to human scrub nurses in real operations and compared to the second SNR. We discovered two remarkable results from the third SNR. One is the targeting time, which is defined as the moment from the end of extraction to the insertion of the next instrument. The third SNR was 1.69 s faster than human scrub nurses in presenting surgical instruments under the kinematic-based feedback control. Currently, we are researching how to control the SNR based on the surgical operating model that we have constructed with UPPAAL [8, 12]. By including this surgical model in the SNR system, it will be able to predict the next instrument that should be used in the next surgical procedure and also be able to work better to provide the best support for high-quality surgical operations.

Abstract

Ca^{2+} signaling is of major importance for a wide range of intra- and inter-cellular processes. In particular, for the immune system, Ca^{2+} regulation is crucial for mast cell degranulation, lysis of infected cells, and essentially all responses initiated by T-cell, B-cell, and Fc receptors. The introduction of the Ca^{2+} indicators, such as the fura-2 and indo-1, by Roger Tsien and collaborators, enables the in-vivo and real time imaging of the intracellular Ca^{2+} concentration. In this work, we utilize active contour and optimal mass transport techniques to collectively estimate the intracellular Ca^{2+} concentration and quantify the shape variations in the T-cells. Our results indicate a potentially interesting positive correlation between the intracellular Ca^{2+} concentration with the variations in T-cell shape.

1. INTRODUCTION

Ca^{2+} signaling is crucial for a wide range of intra- and inter-cellular processes including those of the immune system. Indeed, Ca^{2+} regulation is central for mast cell degranulation, lysis of infected cells, and just about all responses initiated by T-cell, B-cell, and Fc

*Corresponding Author's Email: gaoyi@gatech.edu.

receptors [1]. Since the 1980s, the introduction of the Ca^{2+} indicators such as the fura-2 and indo-1 by Roger Tsien and collaborators [2], enables the in-vivo and real time measurement of the intracellular Ca^{2+} concentration. As a result, researchers are now able to capture the fluorescent images as well as videos, and quantitatively estimate the dynamics of intracellular Ca^{2+} concentration.

In this note, we utilize the 340nm/380nm two channel fluorescent images by collectively analyzing the Ca^{2+} concentration as well as the variation of the shape of the T-cell. Using the active contour method [3], we automatically identify and track the T-cell within the high-speed camera video. After that, based on the optimal mass transport theory [4], we formulate a metric to quantify the “distance” between cell shape configurations. The resulting time-varying Ca^{2+} concentration and the shape metric curves shows an interesting positive correlation, which may provide insight into the study of immunological function of the T-cell.

2. METHOD

In this section, we first describe how to extract and segment a given cell from the 380nm fluorescent image. Then, based on the segmentation, we estimate the Ca^{2+} concentration and the shape change in the cell, and determine the correlation between them.

2.1. Cell Extraction and Tracking

In order to estimate the intra cellular Ca^{2+} concentration as well as to compute the shape of the cell, we have to extract the boundary of the cell from the video. To that end, denote the i -th frame as $I : \Omega \rightarrow \mathbb{R}^+$. It can be observed, for example in Figure 2 in Section 3 below, that the cells appear brighter in the image than their background region. Therefore, we opt to use the region based active contour method (Chan-Vese model)[3] for the cell segmentation due to its ability of both extracting the bright region as well as keeping the boundary relative regular/smooth. Mathematically, the contour is modeled as a simple closed curve in Ω , $C : [0, 1] \rightarrow \Omega$ with $C(0) = C(1)$. The extraction of the cell boundary is accomplished by computing the curve C minimizing the energy functional $E(C)$ given as [3]:

$$E(C) := \int_{\text{inside } C} |I(x, y) - \mu_1|^2 dx dy + \int_{\text{outside } C} |I(x, y) - \mu_2|^2 dx dy + \lambda \int_C ds \quad (1)$$

where μ_1 (μ_2) is the average image intensity inside (outside) the close contour C , respectively. The λ is a positive parameter that controls the smoothness of the resulting contour: large positive λ will result in a smooth cell boundary whereas a small positive λ will capture all the boundary details, at the risk of being influenced by the image noise.

The contour C which gives the minimal $E(C)$ is obtained by solving the variational problem under the level set framework [5]. Specifically, in order to achieve fast processing speed, we used the sparse field level set implementation for the level set evolution [6].

2.2. Ca^{2+} Concentration Estimation

The intra-cellular Ca^{2+} is estimated as the cell image intensity ratio between the 340nm channel and the 380nm channel [2]. Assuming that the cells have been extracted via the preceding segmentation procedure, this can be computed as:

$$a = \int_{\text{inside } C} \frac{I_{340\text{nm}}(x, y)}{I_{380\text{nm}}(x, y)} dx dy \Bigg/ \int_{\text{inside } C} 1 dx dy \quad (2)$$

After this, we compute the temporal shape variation and find interesting correlation with the shape of the cell, which are detailed below.

2.3. Shape Metric and Correlation with Ca^{2+} Concentration

In order to compare the shapes of the cell at different time points, we have to formalize the definition of the concept of “shape”. We adopt the definition of “shape” which measures the geometric property of the object after certain global similarity transformation is removed [7, 8]. Due to the motion of the cell mounting device, such global transformation should be removed from the shape metric computation. After that, the “distance” between two shapes are defined. Various definition for the shape metric have been proposed [9, 10, 11], in this work, the Wasserstein 2-metric derived from the optimal mass transport is used. Mathematically,

$$d(C_1, C_2) = \min_T (W(R_1, T \circ R_2)) \quad (3)$$

where

$$\begin{aligned} \hat{R}_i(x, y) &= \begin{cases} 1 & \text{if } (x, y) \text{ inside } C_i \\ 0 & \text{otherwise} \end{cases} \\ R_i(x, y) &= \frac{\hat{R}_i(x, y)}{\int_{\Omega} \hat{R}_i(x, y) dx dy} \end{aligned} \quad (4)$$

and T is the optimal similarity transformation aligning R_1 with R_2 . It is computed as:

In the equation, the $W(\cdot, \cdot)$ indicates the Wasserstein distance defined as follows. First, we call a diffeomorphism $\mu : \Omega \rightarrow \Omega$ *mass preserving* (MP) if $\forall D \subseteq \Omega$ with $(x, y) = \mu(u, v)$, we have:

$$\int_{\mu^{-1}(D)} R_1(u, v) du dv = \int_D R_2(x, y) dx dy. \quad (5)$$

Via change of variables, this can be rewritten as

$$\det(J_{\mu}(x, y)) R_2(\mu(x, y)) = R_1(x, y), \forall (x, y) \in \Omega \quad (6)$$

where $J_{\mu}(x, y)$ is the Jacobian of μ at (x, y) . This is referred to as the *Jacobian equation*. This equation is highly nonlinear, and may have many solutions. The objective here is to

compute the following distance and find the corresponding optimal transportation map (if it exists), defined in terms of the L^p Kantorovich-Wasserstein functional [4]:

$$W(R_1, R_2) = \inf_{\mu \in MP} \left(\int_{\Omega} |\mu(x, y) - (x, y)|^p R_1(x, y) dx dy \right) \quad (7)$$

The minimization problem defined Equation (7) is highly non-linear and is difficult to solve. The quadratic version of this problem ($p = 2$ in Eq. (7)) has been extensively studied and has a number of approaches devoted to its numerical solution; see [12, 13, 14, 15] and the references therein. Previously, by representing the masses as sum of Dirac delta functions, the linear programming can then be employed in solving the problem [12]. Such scheme is also used to model cell nuclei evolution [15]. However, for 2D images of the size $N \times N$, the complexity of such scheme is $O(N^4)$, which is computationally very heavy for large N . Benamou and Brenier took a different path by casting the original problem to a computational fluid mechanics one [13]. Also in the continuum, Haker *et al.* [14] took another approach. They first constructed a mass preserving map μ_0 not necessarily minimizing the cost in Equation 7. Then, such initial map was iteratively processed so as to remove its curl component accomplished via a non-local first order partial differential equation. For a given mass-preserving initial mapping, the solution of the equation does indeed asymptotically converge to the optimal map [16], but numerically may have a problem that if the initial mapping is “far” from the final optimal mapping. In such a case, the scheme may require many iteration steps to sufficiently reduce the curl. To address such problems, Haber *et al.* discretized the problem first and then formulated a consistent numerical scheme in the discrete domain using sequential quadratic programming [17].

In the quadratic case, one can show that there exists a unique strictly convex function $\tilde{\Psi} : \Omega \rightarrow \Omega$ such that the optimal mapping $\tilde{\mu}$ is the gradient of $\tilde{\Psi}$, i.e., $\tilde{\mu} = \nabla \tilde{\Psi}$ [18]. Plugging this into Equation 6 we have:

$$\det(H_{\tilde{\Psi}}(x, y)) R_2(\nabla \tilde{\Psi}(x, y)) = R_1(x, y), \quad \forall (x, y) \in \Omega \quad (8)$$

where $H_{\tilde{\Psi}}$ is the Hessian of $\tilde{\Psi}$ and Equation 8 is the Monge-Ampere equation. Following [19], $\tilde{\Psi}$ can be solved iteratively by:

$$\frac{\partial \Psi}{\partial t} = \log \left(\frac{\det(H_{\tilde{\Psi}}(x, y)) R_2(\nabla_{(x,y)} \Psi(x, y))}{R_1(x, y)} \right) \quad (9)$$

When Ψ converges to $\tilde{\Psi}$, we have the optimal mapping $\tilde{\mu} = \nabla_{(x,y)} \tilde{\Psi}$, where $\nabla_{(x,y)}$ is the spatial gradient operator.

2.4. Overall Algorithm

Given a series of images (video), we present the overall algorithm for the entire processing pipeline as shown in Figure 1. Specifically, the input to the processing pipeline consists of two video sequences $I_{340nm}(x, y, t)$ and $I_{380nm}(x, y, t)$ (340 nm and 380 nm channels, respectively). The cell segmentation algorithm in Section 2.1 is used to extract the T-cells in each frame of the two video sequences. Then, the Ca^{2+} concentration in each frame is computed and is denoted by $a(t)$. In parallel, the shape of the T-cell in each subsequent frame

Figure 1. Overall flow chart of the proposed algorithm.

is compared with that in the first frame, and is denoted as $S(t) := W(R(t), R(t_0))$. Since we are interested in the trends of $a(t)$ and $S(t)$, not their absolute values, they are normalized by dividing their respective ranges (the difference between maximum and minimum values). Finally, the normalized $a(t)$ and $S(t)$ are compared to show the correlation.

3. EXPERIMENTAL RESULTS

3.1. Cell Extraction

We show in Figure 2 several frames from the video indicating the image condition, cell extraction results, and the shape variance between frames.

3.2. Shape and Ca^{2+} Correlation

The algorithm is tested on a total of 20 data cases. Among them, three results are picked at random and are shown below. From these figures and similarly on others not shown here because of lack of space, we can observe a positive correlation between the two curves. Moreover, it is interesting to observe that the Ca^{2+} concentration change often precedes the shape change. This is more evident when there is a relatively significant change in both curves, such as in Figure 3 around 270-th frame and Figure 4 around 110-th frame.

Figure 2. Frame 10 or 380nm (a) and 340nm (b) channels. Frame 115 or 380nm (c) and 340nm (d) channels. The red contours indicate the extracted cell boundaries. Note that the bright spot on top of the cell is glass beads and is correctly excluded from the cell region. The significant shape change between the frames can be observed.

Figure 3. The Ca^{2+} (red) and shape metric (blue) curves and their respective regression lines. Case 1.

Figure 4. The Ca^{2+} (red) and shape metric (blue) curves and their respective regression lines. Case 2.

CONCLUSION AND DISCUSSION

In this work we proposed a complete pipeline for image and shape analysis for the fluorescent T-cell images. In particular, we have used the Wasserstein 2-metric to measure the

Figure 5. The Ca^{2+} (red) and shape metric (blue) curves and their respective regression lines. Case 3.

shape variation of the T-cells, which shows an interesting correlation with the intracellular calcium concentration.

It is also noted that since both the Ca^{2+} concentration and the shape metric computation depends upon the segmentation of the T-cells, we must consider the question of whether the correlation between the two measures is caused by the common segmentation upon which they are based. One possible way to verify this is to utilize other methods to compute the Ca^{2+} concentration so that the generation of the two curves are decoupled. In this manner, we plan to further examine the correspondence found in this work. Another future research direction involves the quantitative analysis of the correlation between the Ca^{2+} concentration and the shape metric.

Chapter 51

REVISIONAL BARIATRIC SURGERY FOR WEIGHT REGAIN: A PROGRAMMATIC APPROACH

***Eric J. DeMaria^{1,*}, MD
and Meredith A. Grzybowski²***

¹Maryview Medical Center, Suffolk, Virginia

²Maryview Medical Center, Bon Secours Health System, Portsmouth, Virginia

ABSTRACT

Revisional bariatric surgery is a significant endeavor because of higher operative risks and poorer weight loss outcomes than primary procedures. The decision to carry out such surgery must be taken by a multidisciplinary team that confirms that the outcomes of the primary procedure actually are not sufficient and, if this is the case, thoroughly analyzes the causes of failure of the initial procedure. Causes for failure include anatomical factors such as initially poorly performed constructions or, conversely, acquired changes that counteract the activity of a correctly performed surgical procedure. Evaluation of the anatomical imperfection requires specific radiological and endoscopic techniques. Depending on the objective findings in combination with the subjective complaints of the patient an adequate surgical strategy can be searched for.

More often than not however behavioral/dietary flaws constitute the essential part of the failure and must be addressed by patient re-education and behavior modification.

OVERVIEW

Revisional bariatric surgery is a complex and evolving area of traditional bariatric surgery. Although bariatric surgery provides a permanent tool to treat obesity for the majority of patients, we are seeing a growing number return with issues that need to be addressed by multidisciplinary comprehensive treatment strategies. Although there may be surgical

* Corresponding Author's Email: ejdemaria@gmail.com.

options, often the procedures are difficult and often carry greater risk than the primary operation. [1] More importantly, the benefit of the various surgical intervention have not been proven in large cohort studies.

Our primary philosophy is to evaluate the patient's anatomy while asking the question "does this procedure look like it is supposed to look?" In years past, our approach was different in that we, and many others, considered only major technical complications, like staple line disruption, to be of significance. Now we are considering the patient in a comprehensive manner evaluating their eating behavior and whether or not they still receive feedback from their surgical 'tool'. Patients who do not receive feedback from a primarily restrictive procedure such as gastropasty, gastric bypass, or gastric banding are considered likely to have anatomic changes that have led to a suboptimal result. This hypothesis is further investigated by endoscopy and imaging studies as well as comprehensive behavioral evaluation. This information is collated and used to discuss treatment strategies and recommend options.

It is important to remember that, while bariatric surgery leads to complex physiologic changes including changes in gut hormones such as ghrelin, altered metabolic responses including a cancer-cachexia like syndrome, etc. revisional surgery is not undertaken to restore or augment these responses. Despite experience with many hundreds of revisional procedures, we do not know if these procedures manipulate the physiology. Our focus is on the traditional concepts of how bariatric surgery works, i.e., we manipulate restriction and/or malabsorption. It is important to approach a planned revisional intervention in these terms.

CANDIDATES

Patients seek out revisional bariatric surgery for a multitude of reasons, some because they have regained weight, some because they believe their surgery has failed, and some because they experience physical problems that they believe may be related to having bariatric surgery. [2] What is constant, is that nearly all the patients that come to see the bariatric unit are unsatisfied with their current weight and are looking for help to obtain a certain weight loss goal or improve current comorbidities. We primarily see patients with previous gastric bypass since that procedure has been performed open or laparoscopically in our region of the United States for the past 20 plus years. Therefore most of our review will cover our approach to the struggling gastric bypass patient and how we evaluate them.

EDUCATION

Patients start the process by calling our program and are scheduled to attend a bariatric revision seminar. They are then sent a packet of information and paperwork to fill out and return. In addition to a health questionnaire and release of medical information form used to obtain the initial surgery operative note, the paperwork they are asked to fill out also contains a revision testimonial in which we ask patients to describe in their own words why they feel they need a revision of their bariatric surgery. Bariatric revision seminars are held once per month and give patients general information on what to expect with the evaluation process,

types of testing performed, and surgical and non-surgical options for revisional bariatric surgery such as reversal, revision, conversion, and endoscopic procedures. Patients are also provided with information from our program dietician about the nutritional evaluation and key diet principles that bariatric patients should be aware of and follow. Patients are then scheduled for an initial evaluation with the bariatric surgeon.

INITIAL EVALUATION

During the initial evaluation appointment we take the patient's past bariatric history including what type of surgery was performed, what the approach was (open or laparoscopic), when the surgery was done, and who performed the surgery. We also want to know what their initial pre-operative weight was and the lowest weight they obtained post operatively. This is followed up by asking the patient if they experienced any post operative complications, if they still feel the effects of their surgery, if they ever had dumping syndrome, if they continue to have dumping syndrome now, and if they are currently experiencing symptoms of GERD. Often times, patients do not understand when asked if they feel the effect of their surgery and we have to go into further detail asking if they have any sense of restriction with eating, what types of foods they eat, and the quantity and quality of foods they are able to consume. We also often run across patients who do not know what dumping is or who were never educated post operatively on the type of diet they were expected to follow. It follows a common pattern that the further out patients are from initial surgery, the less likely they were to be educated on diet, exercise, side effects, and overall what was expected of them postoperatively. Another factor that is very common among patients seeking out revisional bariatric surgery is the lack of follow up that they had with their initial bariatric program. It would be safe to say that all of the patients we have seen seeking revision have had as little as a 2 year to as much as 25 year gap in follow up.

The most prominent reason for seeking revisional bariatric surgery in the patients we have seen is weight regain, but one patient's regain is not always the same as another. In the initial evaluation appointment we have to evaluate further the factors behind the weight regain. We have seen patients come in with as little as a 20 pound weight regain or patients who have regained past their preoperative weight (>100 lbs.). Another variable is the amount of time in which patients gained the weight. This can vary from less than 6 months to over 10 years.

Much of the time we find that the patient's weight regain has resulted from behavioral factors, but even these can be variable. Some patients developed reactive hypoglycemia that was never diagnosed and are driven to eat whatever is available due to alarmingly low blood sugars. Maladaptive eating is a commonly seen issue among our patient population. Some patients have issues with strictures, marginal ulcers, or chronic nausea and vomiting leading them to eat foods that will easily pass through their pouch and gastrojejunostomy. However, more often than not, many patients are uncomfortable with the feeling of restriction from their initial surgery and try to eat foods that will bypass this restrictive sensation. We have met many patients who honestly believe something is wrong with their surgery because they have an uncomfortable feeling in their chest when they eat certain foods such as meat, bread, or pasta. We often have to remind the patient of the sensation of fullness they experienced in the

immediate post-operative period and relate that to what they are feeling now. Many realize that it is the exact same feeling and that they have been trying to avoid that feeling by eating "slider foods" and foods that will bypass the restrictive nature of their surgery.

ANATOMIC EVALUATION

At their initial evaluation appointment, patients are scheduled for three specific tests which are usually performed within the following 2-3 weeks. These consist of an endoscopic evaluation of the gastric anatomy, barium upper GI, and nutritional laboratory evaluation. If nutritional intake concerns were noted in the patient interview, nutritional evaluation with the dietician is required. For those patients with laparoscopic adjustable bands, an upper GI, to evaluate for band slippage, hiatal hernia, or esophageal dilation, and nutritional lab work is performed. Occasionally endoscopy is used to evaluate for band erosion, but that is often not necessary [3].

The endoscopy is performed by the bariatric surgeon to evaluate the patient's gastric anatomy. Precise measurement of the various key anatomic aspects of bariatric anatomy has been a challenge as we do not have adequate measuring tools such as stick/ruler that can be inserted and used to make measurements during the procedure. One such instrument was previously sold commercially but is no longer available. Currently, measurements are specifically taken during the endoscopy as to the distance from the patient's incisors to the level of the z-line and to the level of the gastrojejunostomy in order to estimate gastric pouch length. We attempt to determine if the pouch is long and narrow (cylindrical) or wide (spherical) in order to make approximate volume calculations. With narrow pouches we estimate pouch width to be the same as gastrojejunostomy diameter and estimate volume in cm^3 according to the formula for the volume of a cylinder, i.e., $\pi r^2 l$. We estimate the diameter of the gastrojejunostomy, typically by retroflexing the scope in the Roux limb and photographing the scope passing across the anastomosis. The scope diameter is used as an internal standard to allow us to estimate the anastomotic diameter, e.g., 2-fold, 3-fold, 4-fold, etc. versus scope diameter (10mm). The surgeon also evaluates the pouch for evidence of hiatal hernia, ulcers, or a gastrogastic fistula, and for potential afferent limb elongation.

A barium upper GI with air contrast is ordered with the additional request of ingestion of a barium tablet and barium meal ingestion at the end of the study. Patients are told to bring 6-8 ounces of cottage cheese with them to the study for preparation of the barium meal. A standard barium upper GI is performed followed by an evaluation using powdered barium mixed with the cottage cheese at a 1:1 concentration that the patient is asked to ingest until feeling full. While patients are often able to ingest between 4 and 6 ounces, sometimes up to 12 total ounces of the barium cottage cheese mixture are actually consumed. A final abdominal x-ray is performed to capture the volume and possible dilation of the pouch with the barium meal. We have tried chunky applesauce as an alternative for those patient that are unable to tolerate cottage cheese due to allergy, lactose intolerance, or refusal due to taste/texture, but the applesauce barium mixture appears to move too quickly through the pouch into the efferent limb before volume estimation can be obtained. There have also been several patients whose gastrojejunostomy was dilated to an extent that the barium cottage cheese mixture emptied too rapidly into the efferent limb and pouch volume estimation was

inaccurate. Overall, this test has been beneficial in providing information on GERD, presence of hiatal hernia, ulcer, possible esophageal dysmotility issues, gastric pouch enlargement and volume, gastrojejunostomy enlargement, and possible afferent limb syndrome due to elongation of the blind end of the Roux limb (candy cane) seen with side to side gastrojejunostomy anastomosis.

SURGICAL STRATEGIES

Patients are brought back into the office after the testing is completed to review their results and determine what options are available to them. If their anatomy is intact, then we refer them for nutritional counseling with our dietician to get back on track with healthy eating habits and continue to follow them on a regular basis for bariatric follow up [1-4].

Patients are treated on an individual basis and plans are made with each patient depending on what was found during testing. Many patients are found to have a sliding hiatal hernia, a dilated gastric pouch, or a dilated gastrojejunostomy and frequently some combination of the 3 is found. At times, additional testing is necessary to determine a course of action for the patient. If significant GERD symptoms are found, esophageal manometry testing may confirm that the lower esophageal sphincter is hypotensive. In that case hiatal hernia repair and modified Dor, Toupet, or Nissen fundoplication may be performed with the degree of fundoplication decided during surgery depending on the technical issues found. Hiatal repair with fundoplication has also proved to be a valuable intervention in American patients whose individual health insurance does not cover any further bariatric treatments as the diagnosis being treated by this intervention is gastroesophageal reflux disease. Patients presenting combination of a dilated gastric pouch and dilated gastrojejunostomy usually continue with the evaluation process for the potential of complete revision of their gastric bypass versus laparoscopic adjustable band placement over their existing bypass. Those patients with dilated gastrojejunostomy alone are considered for revision versus endoscopic plication of the gastrojejunostomy. In laparoscopic band patients suffering significant symptoms of excessive restriction with reflux and typical findings on upper GI the band is often completely deflated in the office. Mostly these patients choose to continue with evaluation for conversion to sleeve gastrectomy or roux-en-y gastric bypass.

BEHAVIOR MODIFICATION

As most patients have regained some amount of weight, whether it be due to maladaptive eating, hypoglycemia, or old habits returning, we require all patients to go through a nutritional evaluation with our dietician. Even if the patient's insurance company does not require a weight loss trial, we will often require patients to complete a minimum of 3 months in a weight loss class to relearn healthy eating habits and behaviors. We have come to require that a patient desiring surgical intervention for weight regain in the absence of a surgical complication must demonstrate a 10% total body weight loss during this time to confirm compliance and behavior change. Healthy eating habits and behaviors are essential for a

successful revisional bariatric surgery, and patients are informed that their compliance with diet and exercise is essential in order to achieve positive results.

SUMMARY

Overall weight loss is less with revisional bariatric surgery and requires more effort on the patient's behalf. Patient selection for bariatric revisional surgery is key for both patient and programmatic success. With a multidisciplinary team and good communication between the patient and that team, success is possible.

Chapter 52

METABOLIC FAILURES AND BARIATRIC PROCEDURES

Pedro Paulo Caravatto*, Tarissa Zanata Petry and Ricardo Cohen

Center for Obesity and Diabetes, Hospital Alemão Oswaldo Cruz,
São Paulo, Brazil

ABSTRACT

There is an increasing body of evidence that bariatric surgery leads to higher remission rates of type 2 diabetes mellitus (T2DM) than any other medical treatment or lifestyle intervention. Several trials published so far comparing the effect of bariatric surgery and best medical treatment on diabetic obese patients have shown that T2DM reached up to 75-80% at the end of the study in the surgical group, although most studies have shown a relatively short period of follow-up.

There is no doubt that bariatric procedures, primarily Roux-en-Y gastric bypass, are more effective at inducing T2DM remission. However, there is a lack of information regarding long-term results for disease control. In this chapter, the authors present long-term results of bariatric surgery over metabolic diseases remission.

INTRODUCTION

During the past decades, the number of individuals with type 2 diabetes (T2DM) in the United States (U.S.) has more than doubled, showing that we are in the midst of an epidemic. Approximately 25.8 million Americans were diagnosed with diabetes (nearly 8.3% of the population), and by 2050 as many as one in three U.S. adults could have diabetes [1-2]. Furthermore, T2DM is the leading cause of kidney failure, non-traumatic lower-limb amputations, coronary heart disease, stroke, and visual impairments among adults in the U.S. [3].

* Corresponding Author's Email: pcaravatto@haoc.com.br.

Aside from high morbidity and premature mortality, T2DM imposes a substantial burden on the economy because of its significant medical costs and indirect costs that are the result of work absenteeism, reduced productivity and unemployment from chronic disability. In 2012, the American Diabetes Association (ADA) estimated that the total national cost of diabetes in the U.S. was \$245 billion, of which more than 70% represented direct health expenditures [1]. This represents a 41% increase when compared to a previous estimate published in 2008 [4]. In addition, there has been a significant increase in health resources usage by people with diabetes. For example, diabetics incur approximately 25% of all U.S. hospital inpatient days, almost one third of all nursing/residential facilities days, and around half of all physician office, emergency department, and hospital outpatient visits. An even worse scenario is reported when analyzing data for a specific age, in particular the elderly [1]. For these reasons, it is estimated that health expenditures for diabetics are 2.3 times higher than they would be in the absence of T2DM.

Prospective longitudinal studies have shown that bariatric surgery is the most effective intervention for obesity and its associated diseases, in particular T2DM, reducing the long-term mortality rate of morbidly obese patients when compared to clinical treatment [5-6].

The improvement of metabolic control in bariatric patients was observed as early as days or weeks after surgical procedure, long before considerable weight loss occurred, indicating a direct anti-diabetic effect of the procedure. Consequently, some operations began to be considered as an option to treat less obese patients with uncontrolled T2DM [7]. As expected, good results regarding metabolic control were obtained in this patient group without significant weight loss, particularly after Roux-en-Y gastric bypass (RYGB) [8-9]. Treatment goals are outlined in Table 1. Nonetheless, only limited information is available regarding long-term effects, recurrence or worsening of metabolic diseases years after surgery, and factors associated with their re-emergence.

Table 1. Treatment goals for T2DM patients

Partial remission	Complete remission
At least 1 year's duration	At least 1 year's duration
No active pharmacologic therapy or ongoing procedures	No active pharmacologic therapy or ongoing procedures
HbA1c < 6.5%	HbA1c 4.5 – 6%
FPG 100 – 125 mg/dL	FPG < 100 mg/dL
Secondary goals include: LDL < 100 mg/dL and blood pressure < 130x80 mmHg	

*HbA1c – glycated hemoglobin.

FPG – fasting plasma glucose.

LDL – low-density lipoprotein.

EFFECTS IN TERMS OF GLYCEMIC CONTROL

We recently published the largest and longest-term study to date to examine the safety and efficacy of RYGB in T2DM patients with BMI between 30 and 35 kg/m². All patients were followed from 1 to 6 years (median 5 years). Main outcomes were safety and T2DM remission, defined as glycated hemoglobin (HbA1c) < 6.5% without medication. All patients had uncontrolled T2DM, despite appropriate lifestyle modifications and use of antidiabetic

medications including or not insulin for at least 1 year. Mean pre-op HbA1c was 9.7% and mean duration of disease was 12.5 years.

T2DM remission was observed in 88% of patients, with a significant reduction of HbA1c (9.7 to 5.9%), despite diabetes medication cessation in the majority of cases.

Improvement of diabetes (HbA1c < 7% with lower doses of oral diabetes medications and no insulin) was achieved in 11% of patients. Only one patient in the entire cohort had no changes in diabetes evolution. All patients experienced significant weight loss at 5 years, however there was no correlation between the amount of weight loss and levels of fasting plasma glucose or HbA1c for the first 5 years.

Beta cell function significantly improved as measured by C-peptide response to glucose load. No mortality, major surgical complication or massive weight loss were reported [9].

At 8 years follow-up, 11 (16.5%) patients with previous T2DM remission were back on antidiabetic drugs, 10 were using metformin alone and 1 patient was using a combination of vildagliptin and metformin. There was no correlation between T2DM recurrence and weight regain. Excess weight loss at 8 years was 69% for this series.

During hospital admission and after discharge, all patients had their T2DM managed according to the following protocols adopted by our institution (Tables 2, 3 and 4).

Table 2. Management of T2DM in the perioperative care (NPO status)

BLOOD GLUCOSE (mg/dL) FROM	BLOOD GLUCOSE (mg/dL) TO	INSULIN (UI)	IV GLUCOSE (g)	ACTION
0	69		10	IV glucose G50% 20mL Capillary blood glucose: 6am, 12pm, 6pm and 12am
180		9		Long-acting insulin once a day
70	99	0		Fast-acting insulin
100	149	0		Fast-acting insulin
150	199	1		Fast-acting insulin
200	249	3		Fast-acting insulin
250	299	5		Fast-acting insulin
300	349	7		Fast-acting insulin
350		8		Fast-acting insulin

A retrospective analysis by Di Giorgi et al. reporting on 42 post RYGB diabetic patients with a medium follow-up of 3 years showed resolution of diabetes in 64% at 6 months, while all patients had their diabetes improved. Pre-operative data showed that mean BMI was 51.4 kg/m² and 34% of the participants were using insulin. At 3 years diabetes recurrence was experienced by 26% of patients with initial resolution and by 20% of patients with initial improvement. This group had lower preoperative BMI compared to those who did not recur. Such findings were not observed in our series, where correlation to weight regain was not observed [10].

Table 3. In-hospital management of T2DM in postoperative care (patients in liquid diet)

1. Metformin 2 g per day (optimized)				
2. DPP4 inhibitors				
<i>BLOOD GLUCOSE (mg/dL) FROM</i>	<i>BLOOD GLUCOSE (mg/dL) TO</i>	<i>INSULIN (UI)</i>	<i>IV GLUCOSE (g)</i>	<i>ACTION</i>
0	69		10	IV glucose G50% 20mL Capillary blood glucose before breakfast, lunch, dinner and before 10 pm Long-acting insulin once a day (bed-time)
180		*		Fast-acting insulin before breakfast, lunch and dinner
70	99	5		Fast-acting insulin before breakfast, lunch and dinner
100	149	6		Fast-acting insulin before breakfast, lunch and dinner
150	199	7		Fast-acting insulin before breakfast, lunch and dinner
200	249	9		Fast-acting insulin before breakfast, lunch and dinner

300	349	13		Fast-acting insulin before breakfast, lunch and dinner
350		14		Fast-acting insulin before breakfast, lunch and dinner
(*) If patient is under insulin treatment prior to surgery, reintroduce 50-70% usual dose of insulin and titrate according to fasting capillary blood glucose (target < 120 mg/dL) and postprandial capillary blood glucose (target < 180 mg/dL)				

* DPP4 - dipeptidyl peptidase 4.

Table 4. Outpatient T2DM management (long-term follow-up)

1. Metformin 2 g per day (optimized)
2. DPP4 inhibitors
3. Insulin If patient is under insulin treatment prior to surgery, maintain same dose used at hospital discharge and titrate according to fasting capillary blood glucose (target < 120 mg/dl) and postprandial capillary blood glucose (target < 180 mg/dl). Clinical practice shows that it usually takes 21 days to withdraw insulin therapy in patients with preserved beta cell function.

* DPP4 - dipeptidyl peptidase 4.

Chikunguwo et al. retrospectively studied 177 patients with T2DM who had undergone RYGB. Patients were followed-up from 5 to 16 years (mean 8.6 years). Complete T2DM remission was observed in 88.7% patients, but 43.3% recurred. In this study, T2DM recurrence was correlated with weight regain. The authors found that percentage of weight

loss, gender, age and severity of T2DM were independent predictors of recurrence. Strongest predictors were insulin therapy and gender [11].

EFFECTS IN TERMS OF LIPIDS CONTROL AND CARDIOVASCULAR OUTCOMES

Metabolic surgery benefits that go beyond glucose control include a positive effect on lipid profile. Increases in high-density lipoprotein (HDL) cholesterol have already been reported one year after RYGB [12, 13], however data are still limited to non-controlled studies in morbidly obese patients. Although the actual role played by HDL in the reduction of cardiovascular risk is still unclear [14], there is some evidence that increase in HDL is associated with a reduced progression of atherosclerosis and hence better cardiovascular outcomes, which constitutes a major benefit from metabolic surgery [15, 16].

We examined other cardiovascular risk factors in diabetic patients with low BMI submitted to RYGB and found that hypertension resolved in 58%, hypercholesterolemia in 64%, and hypertriglyceridemia in 58%. For the entire cohort, mean blood pressure progressively decreased over the course of six years [9]. There was also a significant improvement over the six years in lipid parameters, with progressive reductions in total cholesterol, LDL cholesterol and triglycerides, and increase in HDL cholesterol. These changes led to a 10-year decrease in fatal and non-fatal stroke and myocardial infarction numbers.

Other studies have shown beneficial effects of gastric bypass on diabetes and reduced mortality from heart disease in morbidly obese subjects [16, 17]. A recent report from the Swedish Obese Subjects (SOS) study [18] demonstrated the reduction of myocardial infarction incidence in obese diabetic patients following bariatric surgery. We reported the favorable outcomes of metabolic surgery in low BMI patients that go beyond glycemic control, as indicated by the substantial reductions in hypertension and dyslipidemia, yielding major improvements in predicted CV risk. Our results are similar to small, observational studies from India, China and South America [19, 20, 21], although follow-up in these studies was relatively short.

WHAT IS THE ROLE OF WEIGHT LOSS IN THE INCIDENCE OF CARDIOVASCULAR EVENTS?

Lifestyle interventions to prevent T2DM have not avoided cardiovascular events, including in long-term follow up [22, 23]. Sjostrom et al. [15], in the Swedish Obese Subjects study, a non-randomized prospective study, concluded that, compared to usual care, bariatric surgery leads to a reduced number of cardiovascular events and deaths. One of the most important findings in the Swedish study was the lack of correlation between BMI and cardiovascular mortality and/or events. And, conversely, a positive correlation with fasting plasma insulin levels. The Look AHEAD study [24] showed that intensive lifestyle modification may induce significant improvements in intermediate health indicators, such as body weight, fitness, blood pressure, glycemic control, and lipids. These improved risk factor

profiles, however, did not translate into lower rates of non-fatal myocardial infarction, non-fatal stroke, hospitalization for angina, or death compared with conventional diabetes treatment [25]. Look AHEAD found that people who are obese and suffer from T2DM can lose weight and maintain weight loss with a lifestyle intervention. Although the study found that weight loss had many positive health benefits for patients with T2DM, it did not reduce the number of cardiovascular events. Evidence is increasing that metabolic surgery is more effective than medical or lifestyle interventions for weight loss and diabetes remission. In a recent analysis by Arterburn et al. [26] of severely obese patients with diabetes, the adjusted probability of initial remission was 12 to 24 times greater for the 1395 patients who had bariatric surgery than for the 62322 who received usual medical care alone.

In a recent editorial, the same author [27] stated that the benefits of intensive lifestyle treatment for T2DM were more prominent in patients with early stage diabetes, similar to what was reported in bariatric surgery, showing better results in milder, earlier stage disease. Consequently, a strong argument can be made for considering earlier surgical intervention in moderately obese patients (BMI <30 kg/m²) with early stage diabetes, in particular in those with severe insulin resistance, higher cardiovascular risk and uncontrolled disease. This argument backs up the 2011 International Diabetes Federation (IDF) statement on new perspectives on surgical treatment of uncontrolled T2DM in patients with BMIs between 30 and 35 kg/m² [28].

Timing of metabolic surgery is of the utmost importance for T2DM remission. In a retrospective study, Arterburn et al. [27] found that almost 35% of the patients who went into remission following RYGB redeveloped T2DM within five years of surgery. Predictor factors were poor preoperative glycemic control, insulin use and longer diabetes duration, indicating that the earlier the intervention takes place the better [26]. From the above, one may conclude that the Look AHEAD study fundamentally shows that weight loss does not appear to reduce T2DM-associated cardiovascular disease, but rather enhances the benefit of interventions aimed at improving diabetes (diet, surgery etc.).

IS THERE A SURGICAL TREATMENT OPTION FOR PATIENTS WITH TYPE 2 DIABETES RECURRENCE?

Over recent years, the aim of metabolic/bariatric surgery has changed from weight loss only to metabolic control. So far, there is no recognized definition of what constitutes failure of metabolic surgery, much less an accepted standard of care for patients who fall into this category.

Table 5. Definitions for T2DM recurrence

Partial recurrence	Complete recurrence
HbA1c 6.5-7%, but higher than lowest level reported after surgery	HbA1c > 7% and higher than lowest level reported after surgery
Addition of 1 oral antidiabetic agent	Addition of 2 or more oral antidiabetic agents and/or insulin

*HbA1c – glycated hemoglobin.

Figure 1. T2DM recurrence after laparoscopic adjustable gastric band (LAGB).

Figure 2. T2DM recurrence after sleeve gastrectomy.

Arterburn et al. proposed the following criteria for T2DM relapse after bariatric/metabolic surgery. One or more of the following conditions should be fulfilled: (a) restarting diabetes medication; (b) one or more HbA1c readings $\geq 6.5\%$; and/or (c) one or more fasting glucose values ≥ 126 mg/dl [26]. Interestingly, the authors examined the T2DM relapse rate only among subjects who initially experienced a diabetes remission after surgery (partial or complete).

In this chapter, we propose new criteria for patients who do not fall into the remission category but who had their metabolic conditions improved after surgery and, for unknown reasons, later experienced worsening of their metabolic status. These patients should be considered as suffering from T2DM recurrence (and not relapse), and may be divided into two categories (Table 5).

Patients with T2DM recurrence may be candidates for revisional surgery after optimized clinical treatment (Figures 1, 2, 3).

CONCLUSION

When offering surgical treatment aiming at durable diabetes remission, patient selection and counseling are of the utmost importance. We found that patients with a longer history of diabetes and those under insulin treatment were more likely to relapse than those who were not using insulin or who had had diabetes for less than 10 years. However, not all patients receiving insulin failed to achieve diabetes remission. An earlier surgical intervention clearly appears to be preferable. However, more severely affected and insulin-dependent diabetic patients may benefit from surgery as well, since these patients, although unable to interrupt diabetic medication, may experience improvement in retinopathy, nephropathy, and other diabetes-related conditions. Furthermore, these patients may benefit from a significant improvement in quality of life and experience remission of other metabolic diseases. It is also
